Optical limiting performance of zinc ferrite, nickel zinc ferrite, and copper zinc ferrite nanoparticles is investigated at 532 nm using 5 nanosecond laser pulses. Enhanced optical limiting is observed in the mixed zinc ferrites, which is attributed to the relative longevity of self-trapped charge transfer states. Samples exhibit absorption saturation followed by a rapid onset of optical limiting as the input fluence is increased. This is advantageous in applications where detector sensitivity should be retained at the maximum value until the input fluence approaches the detector damage regime. The Z-scan results are compared to those measured in C60. © 2012 American Institute of Physics. [http://dx.doi.org/10.1063/1.4724194]

It is known that nanomaterials, in general, exhibit altered physical and chemical properties in comparison to their bulk forms.1 This originates from factors associated with size reduction, such as increase in grain boundaries and enhanced surface to volume ratios. Quantum confinement is another aspect that plays an important role in the electrical and optical properties of materials like semiconductor quantum dots.2 Magnetic spinel ferrites (MFe12–xO4, where M = Fe, Co, Mn, Ni, or Zn) are versatile nanomaterials, which find use in several magnetic and biological applications. These structures are characterized by superparamagnetism and tunable surface properties. Optical nonlinearities in ferrites are relatively unexplored, and reports3–5 are rare compared to organics, semiconductors, and metals. Modifications in optical nonlinearity caused by the inclusion of different transition metals into a spinel ferrite system would be of considerable interest owing to applications including optical limiting. Therefore, in the present work, we have studied the nonlinear optical properties of nanosized spinel Zn–ferrite (ZnFe2O4), in comparison to its Ni and Cu mixed forms, namely, NiZn–ferrite (NiZnFe2O4) and CuZn–ferrite (CuZnFe2O4), using the open-aperture z-scan technique.

Ferrites are non-conductive ceramic compounds derived from iron oxides such as hematite (Fe2O3) or magnetite (Fe3O4). They are magnetic in nature, and are extensively used for magnetic recording, and in the construction of inductors, permanent magnets, electrical transformers, and millimeter integrated circuits.5 Due to their unique nonreciprocal and frequency-selective properties, ferrite devices have played a key role in active aperture radar, microwave, and multifunction systems on defense platforms.7 Recently, they have been investigated for magnetic resonance imaging (MRI),8 thermal activation therapy,9 drug delivery,10 and biosensing11 applications.

Crystal structure of ferrites can be described as a close-packed assembly of oxygen atoms with metal atoms occupying the interstitial sites.12 Spinels are a class of ferrites of general formulation A2+3B2+3/2O4, which crystallize in the cubic (isometric) crystal system, with the oxide anions arranged in a cubic close-packed lattice. One unit cell of a spinel ferrite contains eight molecules with twenty four metal positions. Of these, eight are tetrahedral sites and the remaining sixteen are octahedral sites. In the case of Zn–ferrite, tetrahedral sites are occupied by Zn2+ ions and octahedral sites by Fe3+ ions.6 This type of structure where divalent and trivalent cations occupy tetrahedral and octahedral sites, respectively, is called normal spinel.

In this paper, we investigate the optical limiting properties of spherical nanoparticles of ZnFe2O4 and its Ni and Cu mixed forms, which are well dispersed in toluene. Results are compared to those measured in C60 under identical conditions. C60 was chosen for comparison because it is a benchmark material for optical limiting and is extensively studied in literature.13–15 All samples were purchased from Aldrich and used without further purification. The nanoparticles are less than 100 nm in size, and their SEM images taken on a Zeiss ULTRA-55 FEG SEM are shown in Figure 1. The open aperture Z-scan technique16 has been used to determine the optical limiting efficiencies and thresholds, and to calculate the nonlinear absorption coefficient.

Linear absorption spectra of the samples were measured using a UV-VIS (Cary 300 Bio) spectrophotometer (Figure 2(a)). For these measurements, concentrations of approximately 1.4 × 10−4 and 1 × 10−5 mol l−1 were used for the oxide samples and C60, respectively. According to the absorption spectra, ferrite samples do not show definite absorption peaks. However, assuming direct band gap, the band gap energies can be determined from the absorption coefficients (α) near the band edge by using the Tauc relation17,18

\[
\alpha h\nu = A(h\nu - E_g)^{1/2},
\]

where A is a constant that depends on the band structure and the refractive index of the material, h is the Planck’s...
constant, $\nu$ is the frequency, and $E_g$ is the energy gap. By plotting $(x\nu)^2$ versus $\nu$, the band gap energy was determined by extrapolation, as shown in Figure 2(b). The values obtained are 2.3, 2.1, and 2.5 eV, for ZnFe$_2$O$_4$, NiZnFe$_2$O$_4$, and CuZnFe$_2$O$_4$, respectively.

Samples for optical limiting measurements were prepared by dispersing the nanoparticles in 0.005 g ml$^{-1}$ solutions of poly(methyl methacrylate) (PMMA) in toluene. The addition of PMMA helps to stabilize the dispersion. Samples were so prepared that each has the same linear transmission of approximately 52% at the excitation wavelength of 532 nm, when taken in 1 mm path length cuvettes (inset of Figure 2(a)). An Nd:YAG laser (Minilite I, Continuum) emitting 5 ns laser pulses was used as the excitation source. The laser pulse repetition frequency was 0.2 Hz. The laser beam was passed through an iris aperture and pinhole to obtain a clean Gaussian beam. In the open aperture Z-scan, the laser beam is focused using a lens, and the transmission of the sample is measured as a function of the relative position of the sample ($z$) with respect to the beam focus ($z = 0$). We used a plano-convex lens ($f = 100$ mm) for focusing the beam, which had a diameter of about 3 mm. The beam waist at the focal point, as measured by the knife edge method, is $12 \pm 2 \mu m$. In our set up, the sample taken in a 1 mm glass cuvette was mounted on a linear translation stage of 15 cm span and 1 \( \mu \)m resolution (Newport, ILS150PP). The incident and transmitted pulse energies were measured using pyroelectric energy probes (LaserProbe, RjP-735). Z-scans were done at three different incident laser pulse energies, viz. 5, 8, and 12 \( \mu \)J. The open-aperture z-scan curves measured in the samples at the incident energy of 12 \( \mu \)J are shown in Figure 3.

In general, the depth of the valley in the z-scan curve is a direct indication of the optical limiting efficiency of a material. From the z-scans, it is clear that C$_{60}$ exhibits the maximum dynamic range for optical limiting, as it shows a limiting effect throughout the range of measurement. In contrast, the ferrite samples show an increase in transmission in the low and moderate fluence regions, and a deep, efficient limiting at the higher fluences. The limiting efficiency of NiZnFe$_2$O$_4$ and CuZnFe$_2$O$_4$ are better than that of C$_{60}$ at the highest fluences. Even though C$_{60}$ offers protection to the detector for the entire range of input fluences, this may in fact become a disadvantage because the sensitivity of the
protected detector is reduced even for those input fluences, which are lower than its damage threshold. Thus from an application point of view, the ferrite samples have a unique advantage: when properly designed, they can retain or even increase the sensitivity of a detector while it is in its safe operating regime, and switch to sudden limiting when the input fluence exceeds the detector damage threshold. Sudden onset of limiting is sometimes an indication of induced thermal scattering; but from visual inspection and photographic images, we have verified that in the present case, thermal scattering is negligible (inset of Figure 3).

The normalized transmission of the samples \( T(z) \) can be numerically evaluated using the expression\(^{16} \)

\[
T = \frac{1}{\sqrt{q_0}} \int_{-\infty}^{\infty} \ln(1 + q_0 e^{-r^2}) \, dt
\]

with \( q_0 \) given by \( \beta I_0 L_{\text{eff}} [1 + (z^2/z_0^2)] \), where \( I_0 \) is the irradiance at the focus, and \( z \) is the position of the sample, \( z_0 \) is the Rayleigh range given by \( \pi \omega_0^2 / \lambda \), where \( \omega_0(0) \) is the beam radius at focus, and \( \lambda \) is the light wavelength. \( \beta \) is the nonlinear absorption coefficient. \( L_{\text{eff}} \) is given by

\[
L_{\text{eff}} = \frac{1 - e^{-\alpha L}}{\alpha},
\]

where \( \alpha \) is normally the linear absorption coefficient. However, considering the occurrence of kinetic absorption saturation in the ferrite samples, \( \alpha \) is rewritten as

\[
\alpha = \alpha_0 \frac{I_{\text{sat}}}{I_{\text{sat}}},
\]

where \( \alpha_0 \) is the linear absorption coefficient and \( I_{\text{sat}} \) is the saturation intensity. Numerical fits obtained to the experimental data using Eq. (2) are shown in Figure 3, and the calculated values of \( \beta \) and \( I_{\text{sat}} \) are summarized in Table I. In the limited range of pulse energies used, we could not observe any clear dependency of the nonlinear parameters on the energy.

For drawing the optical limiting curves, we note that at any given position \( z \), the energy density (fluence) of a spatially Gaussian beam can be calculated from the laser pulse energy and the beam radius. The beam radius \( w(z) \) is given by

\[
w(z) = w(0) \sqrt{1 + \left( \frac{z}{z_0} \right)^2},
\]

and knowing \( w(z) \), the position-dependent fluence of the Gaussian laser beam can be calculated from the expression,

\[
F(z) = 4(\ln 2)^{1/2} E_{\text{in}} / \pi^{3/2} \omega(z)^2,
\]

where \( E_{\text{in}} \) is the laser pulse energy. From the measured values of the energy transmitted by the samples for different values of \( z \), the variation of the output fluence with input fluence can be determined. Figure 4(a) shows the output fluence, and Figure 4(b) shows the sample transmission, plotted against the input fluence. The optical limiting thresholds \( F_l \) (input fluence at which the transmission drops to 50% of the linear transmission) are 1.16, 1.49, 1.60, and 2.23 J cm\(^{-2} \) for C\(_{60}\), CuZnFe\(_2\)O\(_4\), NiZnFe\(_2\)O\(_4\), and ZnFe\(_2\)O\(_4\), respectively. In comparison, the limiting thresholds of suspensions of C\(_{60}\), carbon nanotubes, and carbon black, prepared with approximately 50% linear transmission at 532 nm, for 7 ns laser pulses, are reported to be 1.0 J cm\(^{-2} \), 1.7 J cm\(^{-2} \), and 1.7 J cm\(^{-2} \), respectively.\(^{20} \)

The observed enhancement in optical limiting efficiency when Cu or Ni is incorporated into Zn-ferrite can be explained using a mechanism involving self-trapping of charge transfer (CT) states. Optical response of 3d metal oxides is dominated by the CT transition between 2p orbital of oxygen and 3d orbital of metal.\(^{21} \) The relaxation of the optically excited CT state is governed by a cumulative effect of both electronic and ionic terms associated with the displacement of electronic shells and ionic core, respectively.\(^{22} \) In a CT unstable system, self-trapping of the CT excited state can occur. This self-trapping mechanism is strongly governed by the lattice strain.\(^{23} \) In the case of nickel and copper zinc ferrite, introduction of Ni\(^{2+} \) and Cu\(^{2+} \) ion into the Zn-ferrite structure can create a distortion in the crystal field and induce strain within the structure. It may be noted that these added ions occupy either the tetrahedral site or octahedral site of the structure depending upon whether the fabrication

method favors normal spinel or inverse spinel. The induced strain enhances self-trapping of the CT states, which results in an increase in excited state life time, and therefore the excited state absorption coefficient. Considering also the fact that thermal scattering is not significant in the samples, it can be concluded that optical limiting observed in these ferrites is related to a reverse saturable absorption (RSA) mechanism involving excited electronic states.

In conclusion, we have investigated optical limiting properties of the spinel ferrite system ZnFe$_2$O$_4$ and its mixed forms NiZnFe$_2$O$_4$ and CuZnFe$_2$O$_4$ at 532 nm using nanosecond laser pulses. Addition of Ni and Cu into the crystalline structure results in an enhanced limiting efficiency, which is attributed to the self-trapping of the charge transfer state, and the resultant increase in excited state absorption. All three samples show moderate absorption saturation at lower input fluences and steep limiting at higher input fluences. In comparison, C$_60$ exhibits limiting throughout the fluence range of investigation. The sudden onset of optical limiting preceded by absorption saturation in the present ferrite samples will be advantageous in critical applications where the sensitivity of the protected detector needs to be retained at the maximum value until the input light fluence reaches the detector damage threshold.
