A COMPREHENSIVE SEVERITY ANALYSIS OF LARGE VEHICLE CRASHES

by

Haluk Laman
B.Sc. Department of Civil Engineering, Cukurova University, 2009

A thesis submitted in partial fulfillment of the requirements
for the degree of Master of Science
in the Department of Civil and Environmental Engineering
in the College of Engineering and Computer Science
at the University of Central Florida
Orlando, Florida

Fall Term
2012
ABSTRACT

The goal of this thesis is to determine the contributing factors affecting severe traffic crashes (severe: incapacitating and fatal - non-severe: no injury, possible injury, and non-incapacitating), and in particular those factors influencing crashes involving large vehicles (heavy trucks, truck tractors, RVs, and buses). Florida Department of Highway Safety and Motor Vehicles (DHSMV) crash reports of 2008 have been used. The data included 352 fatalities and 9,838 injuries due to large vehicle crashes.

Using the crashes involving large vehicles, a model comparison between binary logit model and a Chi-squared Automatic Interaction Detection (CHAID) decision tree model is provided. There were 13 significant factors (i.e. crash type with respect to vehicle types, residency of driver, DUI, rural-urban, etc.) found significant in the logistic procedure while 7 factors found (i.e. posted speed limit, intersection, etc.) in the CHAID model. The model comparison results indicate that the logit analysis procedure is better in terms of prediction power.

The following analysis is a modeling structure involving three binary logit models. The first model was conducted to estimate the crash severity of crashes that involved only personal vehicles (PV). Second model uses the crashes that involved large vehicles (LV) and passenger vehicles (PV). The final model estimated the severity level of crashes involving only large vehicles (LV). Significant differences with respect to various risk factors including driver,
vehicle, environmental, road geometry and traffic characteristics were found to exist between those crash types and models. For example, driving under the influence of Alcohol (DUI) has positive effect on the severity of PV vs. PV and LV vs. PV while it has no effect on LV vs. LV. As a result, 4 of the variables found to be significant were similar in all three models (although often with quite different impact) and there were 11 variables that significantly influenced crash injury severity in PV vs. PV crashes, and 9 variables that significantly influenced crash injury severity in LV vs. PV crashes.

Based on the significant variables, maximum posted speed, number of vehicles involved, and intersections are among the factors that have major impact on injury severity. These results could be used to identify potential countermeasures to reduce crash severity in general, and for LVs in particular. For example, restricting the speed limits and enforcing it for large vehicles could be a suggested countermeasure based on this study.
ACKNOWLEDGMENTS

First and foremost I offer my sincerest gratitude to my supervisor, Dr. Mohamed Abdel-Aty, who has supported me throughout my thesis with his patience and knowledge. I would also like to thank Dr. Omer Tatari and Dr. Mohamed Ahmed for their invaluable suggestions and kind acceptance to be in the committee.

Special thanks to Jaeyoung Lee, Rongjie Yu, and Muamer Abuzwidah for their guidance and help in the use of statistical software. I would like to thank my colleagues and my research group, in particular for their warm companionship and encouragements.

Thanks are also due to all my friends here in Orlando and back home: Akif Sahin, Taha Bal, Mustafa Ozkul, Tolga Ercan, Suphi Civelek, Bugrahan Aslan, Tolga Yardimci, Selcuk Bildik, Mustafa Akdag, and Yunus Emre Acikgonul.

Last but not least, I am eternally grateful for my parents; Mustafa and Sirin, my sisters Mhriban Tugba and Elif Betul and my intended wife Arzu Arslan. Without their love and support I would never have completed this task.

CHAPTER ONE: INTRODUCTION

Deaths, injuries and traffic congestions keep traffic safety as a prominent research topic in the field of transportation engineering. The nature and extent of roadway crashes vary by a wide range depending on roadway types and facility, driver characteristics and land-use patterns among other factors. Since crashes associate with complex interactions of numerous factors, micro level crash analysis (e.g., road specific crash analysis, crash specific safety analysis, event specific analysis) allows more insight for causes of a crash.

According to the Florida Highway Safety and Motor Vehicles the death rate in Florida is 1.5 per 100 million Vehicle Mile Travelled (VMT) (Florida Highway Safety and Motor Vehicles, 2008). From the 363,206 crashes reported, 693,832 vehicles were involved. These caused 2,983 casualties and 199,658 injuries (FHSMV, 2008). Data maintained by the DHSMV (Department of Highway Safety and Motor Vehicles) in 2008 indicated that 282 persons were killed and 9,159 were injured out of 22,277 in crashes involving large vehicles in Florida.
1.1 Research Motivation and Objectives

Studies analyzing crash injury severity often focus on crash frequencies. Multiple factors effect crash frequency and severity.

- roadway geometrics
- traffic conditions
- roadway and environmental conditions
- driver and vehicle characteristics

In this study, these factors are considered in order to make a statement regarding large truck and bus safety in Florida.

As shown in this thesis the factors provided above, that affect the crash frequency and severity, will be analyzed based on crash injury severity through several logistic regression models and a Chi-squared Automatic Interaction Detection (CHAID) decision tree model.

The objective of this study is to focus on the injury severity caused by large vehicles. The LV’s are grouped as heavy trucks, truck tractors, RVs, and buses.

1.2 Organization of the Thesis

The thesis has been organized in the following format. Following the introductory chapter a detailed literature review is provided in chapter two; previous studies conducted in large vehicle crash severity analysis have been
critically reviewed along with the different groups of considered regressors in the corresponding studies. This chapter also summarizes the crash severity analyses from different groups of crashes.

The next chapter (chapter three) describes data preparation steps. Datasets and variables used in the analysis are explained in this chapter. The statistical modeling approach of this study is described in chapter four.

The following chapter (chapter five) provides some preliminary analysis, which includes descriptive statistics from different datasets and distributions of crash factors. This is examined through large vehicle involvement based on severity.

Models and results from the analyses are presented in chapter six. This chapter provides a comprehensive discussion regarding the association (direction and magnitude) of different significant parameter estimates from different models developed in this study. The final chapter consists of the summary, conclusions and recommended future work.
CHAPTER TWO: REVIEW OF LITERATURE

There are two sections in this chapter. A synthesis of literature on the analysis of injury severity of such crashes with particular focus on large vehicle crashes is presented in the first section. The injury severity analysis in traffic safety is a widely researched area. The second section provides also crash injury severity analysis literature for different types of vehicles.

2.1 Large Vehicle Related Crash Injury Severity Analysis

Chang and Mannering (1999) analyzed the injury severity and vehicle occupancy for truck-involved crashes and non-truck-involved crashes of nationwide US data by estimating nested logit models. Variables which significantly increase the severity only for truck-involved crashes are higher speed limits and type of collision. Injury severity is noticeably worsened if the crash has a truck involved. The effects of trucks are more significant for multi-vehicle crashes than single-vehicle crashes. Abdel-Aty and Abdelwahab (2004) also developed the same type of models to show the association between large vehicle type crashes (light truck vehicle, vans, and sport utility vehicles (SUV)) on drivers’ visibility and rear-end collisions. According to the results, drivers’ visibility, speed and inattention have the largest effect on being involved in a rear-end collision.
Khattak et al. (2003) developed binary probit models to examine the injury
severity on large truck rollovers for only single-vehicle crashes. The results
stated that driver behaviors as speeding, use of alcohol or drug, traffic violations
have higher risk factors in single-vehicle truck crashes.

Lyman and Braver in 2003 made exploratory data analysis for 25 years of
US nationwide large truck crashes by exposure measures such as; occupant
fatalities per 100,000 population, per 10,000 licensed drivers, per 10,000
registered trucks, and per 100 million vehicle miles traveled. Trends in occupant
deaths in large truck involved crashes are shown in the results. USDOT (2006)
provided an exploratory analysis conducted to a sample of large truck involved
crashes which all include a fatality or an injury from crash reports for 33 months
at 24 sites in 17 states. As a result, it is shown that 87 % of the crashes have
occurred due to driver actions and poor driving decisions. 13% of the coded
reasons were the weather conditions, or roadway problems.

Cantor et al. (2010) focused on truck prediction modeling using poisson
regression models. Driver age, weight, gender, and employment stability etc. are
significantly related to the likelihood of crash occurrence. Poorly maintained
vehicles have also poor safety performance according to the results.

Numerous researches have been used logistic regression in the crash
severity analysis. Khorashadi et al. (2005) used the 4 years of California crash
data and analyzed by multinomial logit models to determine the differences in
rural and urban driver injury severities (both passenger-vehicle and large-truck driver injuries) in crashes that involve large trucks. Intersection related crashes at rural areas result in a significantly increase in a likelihood of severe/fatal injury. In both area type DUI is the most influential variable to be involved in a severe/fatal crash. It is also shown that geometrics, environmental conditions, and driver actions have also significant effects on severe/fatal crash occurrences.

Nassiri and Edrissi in 2006 made a comparison between neural networks and logit modeling using vehicle crash data on two-lane rural highways for truck crashes. The results of both models have significant factors such as roadways, vehicles, environment, and drivers. The research by Chen and Chen (2011) shows truck driver injury severities’ differences between single-vehicle and multi-vehicle crash types by estimating mixed logit models. In this paper the analysis revealed that several risk factors may lead to more severe injuries of truck drivers such as; age, asleep or fatigued driver, carrying hazardous material, wide median, truck overturn, etc.

A different approach to injury severity analysis was used in Islam and Hernandez’ (2011) study which is random parameters tobit regression modeling with crash rates instead of crash frequency. US nationwide crash database is used. The exposures were truck miles traveled and ton-miles of freight. Road surface condition, road geometry, time, day, and month of the crash were all found significant.
Lemp et al. (2011) said that size and weight regulations of large trucks triggered by safety concerns. They used Heteroskedastic ordered probit models to study the impact of vehicle, occupant, driver, and environmental characteristics on injury severity outcomes for those involved in crashes with large trucks. In the results it is mentioned that non-bright lighting conditions or road surface conditions are increasing the fatality risk of the crashes while the number of truck-trailers are also increasing the likelihood of fatality. The same approach was developed to analyze the injury severities of all persons involved in a large truck crash by Zhu and Srinivasan in 2011. Driver behaviors such as; DUI, illegal drug use, inattention were found to be significant predictors on severity. Drivers’ familiarity with the vehicle is also a significant factor which is also related to the owner is driver variable in this research.

In a different research, Zhu and Srinivasan (2011) analyzed the factors affecting the overall injury severity of large truck crashes of a national recent data sample with empirical models. Results provides numerous significant variables such as; driver distraction (truck driver), alcohol use (car drivers), and emotional factors (car drivers).

Finally, Chang and Chien (2013) used non-parametric Classification and regression tree (CART) method to establish the empirical relationship between injury severity outcomes and driver/vehicle characteristics under 2005-2006 truck involved crash data from national freeways in Taiwan. Results are showing that
drunk driving is the most important determinant for the injury severity of truck crashes on freeways. Vehicle types, number of vehicles involved in the crashes are also significant factors on severity of the truck involved crashes.

2.2 Crash Injury Severity Analysis

Shankar et al. (1996) used a nested logit model to estimate the crash severity on rural freeways with a 5-year data from a 61 km section of a rural interstate in Washington State. The estimation results show that environmental conditions, highway design, crash type, driver characteristics, and vehicle attributes have valuable effect on the crash severity.

Chen (1997) developed a series of discrete categorical analyses to determine the association of crash location, type, and driver variables and the severity of the resulting crash using the HSIS data for the years 1994-1997. Car-semitrailer crashes and rural areas found the most likely types to be involved in a severe crash. Desapriya et al. (2006) compared severity of alcohol related vs. non-alcohol related motor vehicle crashes with odds ratios and CI’s. Also looks at severely damaged vehicles besides of injury severity.

Kuhnert et al. (2000) presented the advantages of non-parametric models such as CART and MARS (multivariate adaptive regression splines) which can provide more informative and attractive models than logistic regression models. Chang and Wang in 2006 also used the CART model from 2001 crash data for
Taipei, Taiwan. The results indicate that the vehicle type is the most significant variable associated with the crash severity. Pedestrians, motorcycle and bicyclists have higher risks of being involved in a severe crash. Das and Abdel-Aty (2009) developed conditional inference forests, which are ensembles of individual CART algorithms, are applied for identifying traffic/highway design/driver-vehicle information significantly related to fatal/severe crashes on urban arterials for different crash types. Alcohol/drugs and higher posted limits contribute to severe crashes.

Artificial Neural Networks are also widely used in severity analysis. Abdelwahab and Abdel-Aty (2002) developed MAP (fuzzy ARTMAP) neural networks to analyze the injury severity for drivers involved in traffic crashes at highways, signalized intersections, and toll plazas. Models for each crash location type show vehicle speed at the time of crash increases the likelihood of high injury severity. Drivers in passenger cars are also more likely to have a severe crash than those who drive vans or pickup trucks. Rural area, nighttime, and drunk driver crashes have also higher risk to be involved in severe crashes according to the results. Abdel-Aty and Abdelwahab (2004) developed another ANN model; MLP (multilayer perceptron), ART (fuzzy adaptive resonance theory) and a calibrated ordered probit model in order to compare based on injury severity level. According to the results; gender, vehicle speed, seat belt use, type of vehicle, point of impact, and area type (rural vs. urban) affect the likelihood of
injury severity levels. Female and/or drunk drivers have higher chances of experiencing a severe injury. Nighttime and rural areas are riskier in terms of driver injury severity. Speeding have positive effect on the severity of the crash (not the speed limit, speed ratio). Finally, Delen et al. in 2006 used eight binary MLP neural networks model to estimate the potentially non-linear relationships between the severity and crash related factors. Seat-belt use, driving under the influence of alcohol or drugs, age and gender of the driver, and vehicle role in the accident found to be influential on the outcome of the crash. The weather conditions did not seem to affect the severity level of injury.

Logistic regression models are the most popular methodology in severity analysis. Al-ghamdi (2002) made the binary dependent variable as fatal or non-fatal in the logistic regression model in order to examine the contribution of several variables to crash severity. Location and cause of crash found the most significant variables. For the cause of crash, speed is the highest level while the road section is the highest level influencing the severity. Binary logit models were also performed by Kieliszewski in 2006 to further scope predictor variables to identify traffic event characteristics with respect to severity level, maneuver type, and conflict type. Another binary logistic regression modeling procedure was used by Sze and Wong (2007) to determine the association between the probability of fatality and severe injury and all contributory factors. Das et al. (2008) used simultaneous estimations as probit and logit models to identify
factors contributing injury severity on intersections on an urban arterial corridor. As a result, more severe crashes occur on blacktop surfaces, and segments with higher speed limit, wider pavement surface, and lower and median AADT. In some cases dry pavement conditions is also significant contributing the severity.

Nevarez et al. (2009) used the logistic regression models in two phases. First phase included all drivers and roadway locations. The second phase involved an extension of these models, controlling by crash types. The crash types models showed important contributing factors such as speeding, use of alcohol or drug, type of vehicle. Huang et al. in 2010 developed multilevel ordered logit model methodology to identify the contribution of influential factors and injury severity level under fog or smoke related traffic crashes. According to the results, higher speed, undivided, no sidewalk, two lane rural roads, and at night without street light crashes are riskier in terms of injury severity level. Theofilatos et al. in 2012 used two binary logistic regression models to estimate the probability of fatality/severe injury versus slight injury inside and outside the urban areas. As a result, involvement of motorcycles, bicycles, and buses were significantly riskier based on severity for outside urban areas, while weather conditions and involvements of buses or motorcycles were significantly riskier inside urban areas.

Ordered probit models are also common in analyzing crash severity. For example; Kockelman and Kweon in 2002 examined the risk of different injury
severity levels with this method under a model structure; all crash types, two-
vehicle crashes, and single-vehicle crashes. According to the results, pickups
and SUV’s are less safe than passenger vehicles under single-vehicle crash
conditions. Light trucks protect their drivers better than any other vehicles. Abdel-
Aty (2003) analyzed driver injury severity levels using the ordered probit and
nested logit modeling methodology. Roadway sections, signalized intersections,
and toll plazas in Central Florida are considered. Alcohol, lighting conditions
affected the severity level on roadway sections’ model. Passenger cars and
those who speed have higher risk to experience a severe crash. Abdel-Aty and
Keller (2005) used the same model and tree-based regression methodology and
adopted in the research to understand the factors that contributes the injury
severity at intersections. Ordered probit model results show that higher speed
limit decreases the severity level while crashes involving a pedestrian/bicyclist
had the highest probability to be involved in a severe crash. Tree-based
regression model also indicates the higher posted limit on the minor roads
significantly affected lower injury severity levels. Haleem and Abdel-Aty (2010)
estimated three approach to analyze the crash injury severity level at three- and
four-legged unsignalized intersections: First, ordered probit model with five levels
of injury severity; second approach is a binary probit model with severe vs. non-
severe injury; and last approach dealt fitting a nested logit model. Results are
showing important effects of traffic volume and driver factors on injury severity.
Last but not least, linear genetic programming (LGP) method is used to
distinguish the relationship of geometric and environmental factors with injury
related crashes and severe crashes by Das and Abdel-Aty (2010). As a result,
dry surface conditions, good pavement conditions, wider shoulders, and sidewalk
widths decrease the severity of crashes. Higher posted limit is found to make the
injuries more possible according to the results of LGP.

</table>
Table 1 provides a summary of some of the reviewed literature. The severity analysis in this thesis follows a similar pattern to the literature that has been presented in this chapter. Logistic regression models and a CHAID decision tree model were developed and analyzed. The prediction power of logistic procedure was compared with CHAID model. In this study, new factors that were not discussed in previous literature were introduced, such as the bus or truck involvement, blacktop/concrete road surface type comparison, shoulder existence of the roadway, and residence of Florida. The preparation of the data used in the models will be presented in the next chapter.
CHAPTER THREE: DATA PREPARATION

The source of data for this study is the Florida Traffic Crash Reports, maintained by the Department of Highway Safety and Motor Vehicles. These crash reports are used by law enforcement officers in Florida to report traffic crashes to the Department of Highway Safety and Motor Vehicles. In this chapter; the DHSMV data, the datasets and the variables used in the analysis will be elaborated.

The crash data have been obtained from the Department of Highway Safety and Motor Vehicles (DHSMV), for year 2008. The DHSMV traffic crash database is a relational database consisting of nine files. Each file deals with a specific aspect of a traffic crash. The files are as follows:

1. Events file; contains general information about the crash event characteristics and circumstances. This is the "parent file" of the database.
2. Vehicles file; contains information about each vehicle and their actions in the traffic crash.
3. Drivers file; contains information about each driver involved and condition or action of the driver that contributed to the crash.
4. Property file; contains information about property (other than vehicles) damaged in the crash
5. Pedestrians file; deals with information on any pedestrians involved in the traffic crash (demographic and casual).

6. Violations file; lists the citations (if any) issued in connection with the traffic crash, by statute number. (limited to the first eight citations issues per party)

7. Passengers file; provides information about any passengers involved in the traffic crash.

8. ComVeh file; contains information about commercial vehicles and carriers involved in crashes.

9. D.O.T. Site Location file; contains additional information about Department of Transportation crash locations occurring on state roads only.

3.1 Preparation of Datasets Used in the Analysis

There were four different datasets used in the modeling procedures. The first dataset (Dataset-A) consisted of the large vehicle (LV) crashes. It was prepared by choosing the crashes which contained at least one LV out of all types in crashes. Second dataset (Dataset-B) only involved the passenger vehicles vs. passenger vehicle crashes. The passenger vehicles (PV) were grouped as automobile, van, light truck, and medium truck. They can be defined as smaller vehicles compared to the LV’s. Third dataset (Dataset-C) was prepared by choosing only the LV vs. PV crashes out of other type of vehicle crashes. Dataset-A is different than dataset-C in which the first may also involve
different type of vehicles which were not defined as LV or PV (i.e. motorcycle, bike, etc.). Dataset-C, only contained LV vs. PV crashes. Last dataset (Dataset-D) was defined as the crashes occurred between LV’s which means that only two or more LV’s were involved in those crashes. The variables taken from the drivers’ file of DHSMV were all chosen for the LV drivers for these crash datasets except of dataset-B which is LV vs. LV crashes dataset. In dataset-B, driver characteristic variables were not LV drivers’ but one of the involved PV drivers’ characteristics. Exploratory analyses and five different modeling procedures are estimated using the above mentioned four datasets.

Missing values were found for many of the variables. The value of certain variables could be more likely to be missing for severe crashes while the value of other variables could be more likely to be non-severe crashes. Therefore, removing the missing values would skew the sample. So, it is chosen to retain all cases by imputing with the most frequent level of each variable.

3.2 Predictor and Response Variables Considered in the Analysis

In this study, the variables used in the models are crash injury severity, type of vehicle, lighting condition, weather, rural/urban, owner is driver, residence code, road surface type, road surface conditions, type of shoulder, alcohol/drug use, site location, on-off roadway, divided/undivided highway, total number of vehicles, posted speed. These variables were defined as follows.
• Crash injury severity: This variable is from the events file. So, it contains every person involved in the crash. The levels are as seen in Table 1. The dummy codes are also given as it is used in the models. Incapacitating and fatal levels are grouped as severe crashes while the rest of the levels are defined as non-severe.

- On-off roadway: This variable is taken from the events file. The dummy codes for the modeling is as follows; on roadway (0), off roadway (1).

- Divided/undivided highway: This variable is taken from the events file. The dummy codes for the modeling is as follows; divided highway (0), undivided highway (1).

- Total number of vehicles: This variable is taken from the events file. It is the sum of all vehicles involved in the crash. In this research it was used...
as; more than two vehicle involved crashes (code: 1) and two or less vehicles involved in the crash (code: 0).

- Posted speed: This variable is taken from the vehicles file in order to code the speed variable as crashes occurred on less than 45 mph posted speed limit roadway (code: 0) or more than 44 mph posted speed limit roadway (code: 1). The classification is based on the median (46 mph) of the speed limits.

- Involved vehicle type: This variable is prepared for the dataset of the severity analysis of large vehicle involved crashes. The description of the levels for this variable is as seen in Table 12.

The preparation of datasets used and variables conducted in crash injury severity analysis have been elaborated in this chapter. The methodology used for the modeling procedures will be explained in the next chapter.
CHAPTER FOUR: METHODOLOGY

The statistical models used in this thesis are binary logistic regression and CHAID decision tree procedure. In this chapter these two model methodologies will be explained.

4.1 Binary Logistic Regression Model

In order to analyze the crash injury severity in large vehicle involved crashes, binary logistic regression models were estimated with the consideration of statistically significant factors.

The formula of the logistic model is as follows (Greene, 2003):

\[
\text{Prob}(Y = 1|x) = \frac{\exp^{x\beta}}{1 + \exp^{x\beta}}
\]

where \( \beta \) is a vector of the coefficient estimates of the parameters and \( X \) is a vector of independent variables. Odds ratio is a measure of association which approximates relative risk or in other words, how much more likely it is for the outcome to be present among those with \( x = 1 \) than among those with \( x = 0 \). (Hosmer and Lemeshow, 2000)
4.2 Chi-squared Automatic Interaction Detection (CHAID) Decision Tree Model

CHAID uses a Chi-square splitting criterion as indicated by its name. More specifically, it uses the p-value of the Chi-square:

\[ \chi^2 = \sum \frac{(O - E)^2}{E} \]

O: the frequencies observed.
E: the frequencies expected.

The main characteristics of CHAID are:

1. CHAID determines for each potential predictor the optimal \( n \)-ary split it would produce at each node, and selects the predictor on the basis of these optimal splits. (Ritschard, 2010).

2. The search for a split on an input peaks gradually. Initially a branch for each value of the input signal is assigned. Branches merged alternately split and again seems justified by the p-values. The CHAID algorithm by Kass ends when no merge or split again provides a corresponding p-value. The last split is adopted. An alternative, sometimes called the exhaustive process still divides merge to form a binary split, and then takes the split with the lowest p-value among all the algorithms considered. Once a split is assumed for an input, its p-value is adjusted, and the input with the best matched p-value is selected as the split variable. When the p-value is set to be smaller than a threshold the user
specified, then the node is split. When all the adjusted p-values of the splitting variables in the unsplit nodes are above the user-specified threshold, the tree construction ends.

The two methodologies of models have been described in this chapter. The next chapter will be providing descriptive statistics.
CHAPTER FIVE: PRELIMINARY ANALYSIS

This chapter presents the preliminary exploration of the nature and characteristics of the variables in the final prepared datasets which were described in Chapter 3. The preliminary analysis included descriptive statistics and exploratory analysis for the crashes involving large vehicle, only large vehicle crashes, large vehicle vs. personal vehicle crashes, and only personal vehicle crashes.

There are 22,632 crashes involving large vehicles (LV) and 265,848 crashes not involving LV’s. So, the LV involved crashes are 8% of the whole population of crashes. The incapacitating and fatal crash proportions in crash frequencies of LV and non-LV crashes are provided in Figure 1. The percentage of incapacitating crashes in the LV is slightly less than the non-LV crashes while the LV crashes have higher proportion of fatal crashes.

![Figure 1: Distribution of LV Involvement by Incapacitating and Fatal Crash Percentages](image)
A distribution of crash groups, such as LV (large vehicle) vs. LV, single LV, LV vs. PV, LV vs. motorcycle, and LV vs. bike/ped/moped, by severe crash (incapacitating and fatal) proportions out of the number of crashes for each group is provided in Figure 2. The number of crashes occurred for each group is as follows:

- LV-LV: 2,662 (severe: 92),
- Single LV: 3,368 (severe: 125),
- PV-LV: 16,356 (severe: 844),
- LV-bike/ped: 92 (severe: 35),

The LV vs. motorcycles have the largest percentage of being severe crashes while LV vs. LV crash groups have the smallest percentage of being a severe crash.

Figure 2: Distribution of Crash Groups by Severe Crash Percentages
Table 14 provides the Chi-square and p-values of variables by crash groups such as; large vehicle (LV) vs. LV, LV vs. passenger vehicle (PV), and PV vs. LV. The non-severe and severe crash frequencies are used in these descriptive statistics.

</table>

The p-values indicate that the lighting conditions, rural-urban, blacktop-concrete, intersection, on/off roadway, number of vehicles, and speed limit variables are associated with the severity of vehicle involvement types at the 90% confidence (α=0.10). It is also shown that DUI and shoulder existence are variables significant (α=0.10) in both cases (LV vs. PV, PV vs. PV). Bus/truck variable is only significant (α=0.10) in LV vs. PV crashes. And finally, road surface conditions and 'owner is driver' variables are only significant for PV vs.
PV crashes. The distributions of these variables by vehicle involvement type severe crash percentages are illustrated in the following figures.

According to Table 14 lighting conditions are associated with the severity of vehicle involvement types at the 99% confidence (α=0.01). The non-bright conditions, severe crash percentages are higher than bright conditions as shown in Figure 3. The LV vs. PV crashes have the highest proportion of severe crashes at non-bright lighting conditions.
Figure 4: Distribution of Area Type by Severe Crash Percentages of Crash Groups

Table 14 shows that the area types are associated with the severity of vehicle involvement types at the 99% confidence (α=0.01). Severe crash percentages for rural areas are higher than the percentages for urban areas in three of the distributions as shown in Figure 4. The PV vs. PV crashes have the highest proportion of severe crashes at rural areas.
According to Table 14, the 'owner is driver' variable is associated with the severity of PV vs. PV crash group at the 99% confidence ($\alpha=0.01$). The severe crash percentages of non-owner drivers in LV vs. LV, and LV vs. PV crashes are higher than the owners. The percentages of severe crashes of owners of the vehicles are higher than the non-owners of the vehicles in PV vs. PV crashes as shown in Figure 5. It is also shown that PV vs. PV crashes have the highest proportion of severe crashes in terms of the variable 'owner is driver'.
Figure 6 shows the distribution of blacktop/concrete road surface types by severe crash percentages of crash groups. Table 14 shows that the blacktop/concrete road surface types are associated with the severity of vehicle involvement types at the 90% confidence (α=0.10). The severe crash percentage of blacktop (asphalt) surface type is higher than it is in concrete surface types as shown in Figure 6. The PV vs. PV crashes have the highest proportion of severe crashes at blacktop surface type.
According to Table 14, it is seen that the shoulder existence of the roadway is associated with the severity of LV vs. PV and PV vs. PV vehicle involvement types at the 99% confidence (α=0.01). Experiencing severe crash percentages of roadways without shoulders are higher than roadways with shoulders as shown in Figure 7. PV vs. PV crashes have the highest severe crash proportion at roadways without shoulders.
Table 14 indicates that the condition of the roadway surface is associated only with the severity of PV vs. PV vehicle involvement type at the 99% confidence ($\alpha=0.01$). In PV vs. PV and LV vs. LV crashes’ severe percentages of dry road conditions are higher than bad road conditions while in LV vs. PV, bad condition severe crash percentages are higher as shown in Figure 8.
According to Table 14, the alcohol/drug use of drivers is associated with the severity of LV vs. PV and PV vs. PV vehicle involvement types at the 99% confidence (α=0.01). Drivers which are driving under the influence of alcohol or drugs (DUI) have higher proportions of severe crashes than the ones not using alcohol or drugs while driving as shown in Figure 9. The LV vs. PV crashes have the highest proportion of severe crashes of DUI drivers.
Table 14 shows that the intersections are associated only with the severity of vehicle involvement types at the 95% confidence ($\alpha=0.05$). The severe crash percentages at intersection related locations are higher than non-intersection locations as shown in Figure 10. The PV vs. PV crashes have the highest proportion of severe crashes at intersections.
According to Table 14, the on/off roadway variable is associated with the severity of vehicle involvement types at the 99% confidence ($\alpha=0.01$). The severe crash percentages on roadway have higher proportion than off roadways in LV vs. LV and LV vs. PV crashes while off roadways have higher severe crash percentages in PV vs. PV crashes as shown in Figure 11. In addition, the PV vs. PV crashes have the highest proportions of severe crashes at on/off roadway crashes.
Table 14 indicates that the number of vehicles involved is associated only with the severity of vehicle involvement types at the 90% confidence ($\alpha=0.10$). Severe crash percentages of more than 2 vehicles involved crashes are higher in all crash types as shown in Figure 12. The LV vs. PV crashes have the highest proportion of severe crashes with more than 2 vehicles involved.
According to Table 14 the maximum speed limit is associated with the severity of vehicle involvement types at the 99% confidence ($\alpha=0.01$). The severe crash percentages of roadways with higher ($\geq45\text{mph}$) speed limits are higher than roadways with lower ($<44\text{mph}$) speed limits as shown in Figure 13. The PV vs. PV crashes have the highest proportion of severe crashes at high speed limits.

Descriptive analysis as well as distributions for each variable by vehicle involvement types were provided and described in this chapter. The following chapter will be dealing with the models and their results which will involve several statistical models with similar datasets used in this chapter.
CHAPTER SIX: MODELS AND RESULTS

After the exploratory analysis of the crashes involving large vehicles’ injury severity provided in the preliminary analysis chapter, the modeling procedures are presented in this chapter. This chapter has been divided into two major sections. First section deals with two different types of models under dataset-A which is large vehicle involved crashes considering numerous predictor variables based on injury severity as a response variable. The second section discusses the modeling of PV vs. PV crashes (dataset-B, model-A), LV vs. PV crashes (dataset-C, model-B), and LV vs. LV crashes (dataset-D, model-C) again based on the injury severity as a binary outcome. A modeling structure has been developed with these three crash datasets in order to compare the contributing factors. SAS® and SAS Enterprise Miner® software programs have been used for the analysis conducted in this chapter. Both sections provide separate discussion for the modeling results.

6.1 Severity Analysis of Large Vehicle Involved Crashes

In this section a binary logistic regression model and a CHAID decision tree model were fitted to establish relationships between large vehicle involved crash events characteristics and injury severity. The severe crashes are defined as incapacitating and fatal crashes as it is mentioned in Chapter 3. The dataset
has 1,096 severe crashes out of 22,631 observations. Due to large difference between non-severe and severe crash frequencies the dataset is normalized by sampling. The sampling procedure uses all the observations with the rare occurrence (severe crashes), and then takes a random sample of the remaining data. A 30 percent to 70 percent proportional split was used which means that the final data have 30% and 70% severe and non-severe crashes respectively. There were 3653 observations and 1,096 severe crashes after sampling the raw data. No noteworthy differences detected in the significant variables between the models before and after the sampling procedure. First, the binary logit modeling procedure is explained and the results are discussed. Secondly, the CHAID decision tree modeling procedure is elaborated with the results. Finally, a model comparison is presented at the end in order to evaluate the two modeling procedures in terms of prediction power.

6.1.1 Binary Logistic Regression Model

In this model, severe vs. non-severe crashes were used as a binary outcome. Table 15 summarizes the model results. The p-values are shown to identify significant variables in the model. Three measures of goodness-of-fit, e.i. likelihood ratio, score and Wald Chi-square, of the model were used to show the statistical significance of the model at significance level less than 0.001. The alpha levels for each variable are also defined in Table 15 in order to understand
the confidence intervals of the probabilities for severity. Receiver Operating Characteristic (ROC) curve of the model is a graphical plot which illustrates the performance of a binary classifier system as its discrimination threshold is varied. Regarding predictive power, c (the area under ROC curve) has a value of 0.754. The methodology of binary logit modeling procedure is presented in chapter 4.

The significant variables are shown in Table 15; crash groups based on vehicle types involved, residence code of the driver, roadway surface type, shoulder existence of the roadway, maximum speed limit, area type, driving under influence of alcohol or drugs, lighting conditions, owner is driver, on/off roadway crashes, intersection related crashes, number of vehicles involved, and bus or truck. The group of crashes based on the vehicles involved is a nominal variable with 5 levels which are PV vs. LV crashes (1), single LV crashes (2), bike/pedestrian/moped vs. LV crashes (3), and motorcycle vs. LV crashes (4) and the base level, LV vs. LV crashes (0).

*** Significant at $\alpha=0.01$, ** Significant at $\alpha=0.05$, * Significant at $\alpha=0.10$

“In all cases, base conditions are defined as zero”
6.1.1.1 Discussion of Results

With respect to the significant factors found in this model, LV vs. LV crashes are more likely to be severe compare to the PV vs. LV crashes. Single large vehicle crashes have less probability, involving in a severe crash in contrast to LV vs. LV crashes while bike/pedestrian/moped vs. LV crashes, as well as the motorcycle vs. LV crashes have more probability involving in a severe crash than the base type of crash. The single LV crashes vs. LV-LV crashes result is also consistent with the study of Chang and Mannering (1999). It is also found that the residency of the driver has a negative effect on the severity, means if the driver is a resident he/she is a riskier driver in terms of severity. Moreover, road surface type variable was defined as blacktop or concrete and the model estimates that the blacktop surface type is riskier compare to concrete surface types. Roads without shoulders have a positive effect on severity. Posted speed is another significant factor which is showing the roadways with speed limits of 45 mph or higher are more risky in terms of crash severity. Severe crashes are more likely to occur in urban areas comparing to rural areas. Driving under influence of alcohol or drugs increases the risk of being involved in a severe crash. Non-bright lighting conditions such as nighttime without a streetlight, and dusk/dawn times have positive effect on the severe crashes. It is more likely to be involved in a severe crash for the driver who is the owner as well of the vehicle. On roadway crashes, intersection related crashes, and crashes involved more than
two vehicles are also more likely to be severe crashes. Large trucks are riskier in contrast to buses according to the LV involved crashes severity model results.

6.1.2 CHAID Decision Tree Model

CHAID decision tree modeling procedure has been conducted to dataset-A (LV involved crashes). The decision trees give the importance of variables, in addition to help the analyst to better interpret the results. The advantage of using trees in severity analysis is that it helps to determine the values of parameters contributing more to the severity. A series of predictor variables found significant affecting the qualitative target variable of injury severity level in an attempt to identify the important patterns of the LV involved crashes. Predictor variables were presented in Table 16. Figure 14 provides the results of the CHAID decision tree map, which has 14 terminal nodes. It shows that the variables used in this model are the primary splitters in the decision tree, implying that these variables were critical in classifying the injury severity for LV involved crashes.
Figure 14: CHAID Decision Tree Map
6.1.2.1 Discussion of Results

The interpretation of CHAID results is straightforward. The initial split at node 1 is based on the variable of posted speed limit. This indicates that the single best variable to classify the injury severity of LV involved crashes is whether or not occurred at roadways with 45mph or more posted speed limit. CHAID directs the crashes occurred at 45mph or more speed limited to the left, forming node 2 and those crashes occurred at speed limit below 45mph to the right, forming node 8. CHAID further splits node 2 based on the multivehicle crashes variable and directs the crashes involved more than two vehicles to the left, forming node 3; one or two vehicle involved crashes to the right, forming node 4. CHAID further splits node 3 based on lighting condition variable and directs the crashes occurred in non-bright light to left, forming terminal node 1; crashes in bright light conditions to the left, forming terminal node 2. As indicated by terminal node 1, if the crash occurred at 45mph or more speed limited roadway with more than 2 vehicles with non-bright light conditions, the tree predicts the severity of injury to this crash is most likely to be severe (85.1%). At terminal node 2, the tree predicts that more than two vehicles involved crashes at high speed limits with bright light conditions the crashes are more likely to be severe (55.6%). The tree further splits node 4 to who was involved in a crash while driving under influence to right, forming terminal node 7; who is not DUI to
the left, forming node 5. Terminal node 7 is showing that crashes occurred at high speed limits with one or two vehicles are 83% more likely to be severe if the driver is DUI. CHAID splits node 5 based on lighting condition again and directs the non-alcohol or drug used drivers to bright light conditions, forming node 6; non-bright conditions to terminal node 6. CHAID predicts that terminal node 6 has 50.7% probability to be a severe crash. At node 6 the data is split based on the involved vehicle type to the crashes. Terminal node 5 is likely to be severe (80.8%). CHAID further split node 7 based on area type. Terminal node 3 which is the crash occurred at 45mph or more speed limited roadway with more than two vehicles and been used under influence of alcohol or drugs with bright light conditions at urban areas have 36.8% probability to be severe crashes while rural areas have 26.4% at terminal node 4. The prediction of injury severity likelihood can be obtained by continuing down the tree branches, with this splitting rule, until a terminal node is reached.

According to the right side of the tree (i.e., nodes 8–12 and terminal nodes 8–14) for the crashes occurred at low speed limits, 5 of the 7 terminal nodes (except for terminal nodes 10 and 14) show that the injury severity is most likely to be no-injury regardless of what the contributing factors are. For example, terminal node 9 which is LV vs. PV or single LV (1 or 2 vehicle involved) crashes occurred at low speed limits have 37.3% probability of being a severe crash. It can be clearly seen that the injury severity likelihoods predicted by the crashes
occurred at higher speed limits are substantially more severe than those by the lower speed limits. This indicates that speed limit of the roadway the crash occurred is the most influential factor to severity. Table 16 is providing the predicted importance of the variables by CHAID. With respect to the importance order, the type of vehicle involved to the LV crash is following the speed limit variable. More than two vehicle involvement, DUI, lighting condition, area type, and intersection relation of the crashes are following variables respectively in the CHAID importance order.

6.1.3  Model Comparison of Logistic Regression and CHAID Decision Tree

In this section, a comparison between the binary logistic regression model and CHAID decision tree model will be presented. Both models were conducted to the LV involved crashes dataset. The prediction powers of two models were determined by the area under the ROC curve. The sum of squared errors was also provided for each model. Figure 15 is providing the ROC curves in one
sensitivity-specificity diagram. The areas under the ROC curves (c-value) are provided in Table 17.

**Table 17: Statistical Models by Area under the ROC curve (c-value)**

<table>
<thead>
<tr>
<th>Model</th>
<th>Area (c-value)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Logistic Regression Model</td>
<td>0.754</td>
</tr>
<tr>
<td>CHAID Decision Tree Model</td>
<td>0.744</td>
</tr>
</tbody>
</table>

The sum of squared error for the regression model is 1266.618, while the tree models’ is 1279.527.

As a result, both the areas under the ROC curves and squared errors of the regression model seem better in terms of prediction power compare to the
CHAID decision tree model. However, there is a difference in the number of significant factors. CHAID could have a higher prediction power with greater number of covariates. Hence, these two methodologies are comparable.

6.2. Severity Analysis of a Modeling Structure

This section has three binary logistic models based on a modeling structure. Dataset-B (PV vs. PV crashes), dataset-C (PV vs. LV crashes), and dataset-D (LV vs. LV crashes) were used to estimate three models respectively, PV vs. PV (model-A), PV vs. LV (model-B), and LV vs. LV (model-C) binary logistic regression models. Data preparation of each type of crash dataset was explained in chapter 3. The PV's and LV's were grouped as followed by the “type of vehicle” variable in vehicle dataset of DHSMV crash reports.

Passenger Vehicle: Automobile, Van, Light Truck (Pick-up, 2 or 4 rear tires), Medium Truck (4 rear tires).

Large Vehicle: Large Truck (2 or more rear axles), Truck Tractor (Cab-Bobtail), Motor Home (RV), Bus (driver + seats for 9-15), Bus (driver + seats for over 15).
The modeling structure was built in order to compare and contrast the three different crash group datasets. Regarding the results of three models, the significant variables will be elaborated to compare the differences among these crash groups and find the uniqueness for each of them in terms of injury severity at the end of this section.

### 6.2.1 Personal Vehicle vs. Personal Vehicle Crashes Model

In this section a binary logistic regression model (model-A) fitted to dataset-B (PV vs. PV crashes) which is the crashes only between/among passenger vehicles based on injury severity. The dataset has 17,502 severe crashes out of 265,848 observations. Due to the large difference between non-severe and severe (severe: incapacitating and/or fatal) crash frequencies the
dataset is normalized by sampling. The sampling procedure uses all the observations with the rare occurrence (severe crashes), and then takes a random sample of the remaining data. A 30 percent to 70 percent proportional split is used which means 30% of the data is severe and 70% is non-severe crashes. There were 58,340 observations and still 17,502 severe crashes after sampling the raw data. No noteworthy differences detected in significant variables between the models before and after the sampling procedure.

In the model, severe crashes vs. non-severe crashes were used as a binary outcome. Table 18 summarizes the model results. The p-values are shown to identify the significant variables in the model. Three measures of goodness-of-fit of the model, likelihood ratio, score and Wald Chi-square, show the statistical significance of the model at significance level less than 0.001. The alpha levels for each variable are also defined in Table 18 in order to understand the confidence intervals of the probabilities for severity. Regarding predictive power, c (the area under ROC curve) has a value of 0.660.

*** Significant at α=0.01, ** Significant at α=0.05, * Significant at α=0.10
“In all cases, base conditions are defined as zero”

This model has eleven significant factors contributing the injury severity outcome. The variables used in this model were elaborated in Chapter 3. These variables are respectively; shoulder existence, maximum speed limit, area type,
driving under influence of alcohol or drugs, lighting conditions, roadway surface type, roadway surface condition, on/off roadway crashes, owner is driver, intersection related crashes, and number of vehicles involved. The results will be explained in the discussion of results.

6.2.2 Large Vehicle vs. Personal Vehicle Crashes Model

There is a binary logistic regression model (model-B) fitted to the dataset-C which is the crashes only between/among Large Vehicles and Passenger Vehicles based on severity. The dataset has 846 severe crashes out of 16,448 observations. The large difference between non-severe and severe (severe: incapacitating and/or fatal) crash frequencies leads to normalize the dataset by sampling. The sampling procedure uses all the observations with the rare occurrence (severe crashes), and then takes a random sample of the remaining data. A 30 percent to 70 percent proportional split is used which means 30% of the data is severe and 70% is non-severe crashes. There were 1,974 observations and still 846 severe crashes after sampling the raw data. No noteworthy differences detected in significant variables between the models before and after the sampling procedure.

In the model, severe crashes vs. non-severe crashes were used as a binary outcome. Table 19 summarizes the model results. The p-values are shown to identify the significant variables in the model. Three measures of
goodness-of-fit of the model, likelihood ratio, score and Wald Chi-square, show the statistical significance of the model at significance level less than 0.001. The alpha levels for each variable are also defined in Table 19 in order to understand the confidence intervals of the probabilities for severity. Regarding predictive power, c (the area under ROC curve) has a value of 0.733.

“In all cases, base conditions are defined as zero”
This model has nine significant factors contributing to the injury severity outcome. The variables used in this model were elaborated in Chapter 3. These variables are respectively; shoulder existence, maximum speed limit, area type, driving under influence of alcohol or drugs, lighting conditions, owner is driver, on/off roadway crashes, intersection related crashes, and number of vehicles involved. A detailed explanation of the results will be provided in the discussion of results.

6.2.3 Large Vehicle vs. Large Vehicle Crashes Model

A binary logistic regression model (model-C) fitted to the dataset-D which is the crashes only between/among Large Vehicles based on injury severity. The dataset has 61 severe crashes out of 2,692 observations. Due to the large difference between non-severe and severe (severe: incapacitating and/or fatal) crash frequencies the dataset is normalized by sampling. The sampling procedure uses all the observations with the rare occurrence (severe crashes), and then takes a random sample of the remaining data. A 30 percent to 70 percent proportional split is used which means 30% of the data is severe and 70% is non-severe crashes. There are 203 observations and still 61 severe crashes after sampling the raw data. No noteworthy differences detected in significant variables between the models before and after the sampling procedure.
In the model, severe crashes vs. non-severe crashes were used as a binary outcome. Table 20 summarizes the model results. The p-values are shown to identify the significant variables in the model. Three measures of goodness-of-fit of the model, likelihood ratio, score and Wald Chi-square, show the statistical significance of the model at significance level less than 0.001. Regarding predictive power, c (the area under ROC curve) has a value of 0.866.

“In all cases, base conditions are defined as zero”

There are four significant factors contributing to the injury severity outcome. The variables used in this model were elaborated in Chapter 3. These
variables are respectively; maximum speed limit, area type, lighting conditions, and intersection related crashes. The results will be explained in detail in the discussion of results.

6.2.4 Discussion of Results

The results of three models in the modeling structure will be discussed in this section.

With respect to the significant factors in model-A; roadways without shoulders, blacktop road surface type compare to concrete, and dry road surface conditions are more likely to have severe instead of non-severe (No injury, Possible Injury, Non-incapacitating evident injury) crashes. Posted speed limit (1, \(\geq 45\text{mph};\) 0, \(<44\text{mph}\)) is the most significant factor in model-A in terms of coefficients, which has a positive effect on the crash injury severity. Rural areas are more likely to experience more severe crashes than urban areas. Driving under influence of alcohol or drugs is also found to increase the injury severity of PV vs. PV crashes. The crashes occurred in non-bright lighting conditions (dark without street light, dusk, and dawn) have positive effect on injury severity. Moreover, off roadway crashes, intersection related crashes and more than two vehicles involved crashes were found to have positive affect the injury severity of PV vs. PV crashes. Last but not least, the ‘owner is driver’ is a significant factor which can be concluded as owner of the vehicle is more likely to be involved in a
severe crash. This could be explained as the large vehicles are mostly commercial vehicles. So, the drivers are most likely not to be the owners of the vehicles.

Regarding to the results of model-B; shoulder existence of the roadway, posted speed limit, rural vs. urban, driving under influence of alcohol or drugs, lighting conditions, intersection relation, and more than two vehicles involvement variables can be concluded in the same way with the model-A results, mentioned above. Nevertheless, there are two factors with opposite signs which mean they don’t have the same affect. First, on roadway crashes instead of off roadway crashes are more likely to be severe for LV vs. PV crashes. And second is the owner is driver variable which is concluded as the non-owner of vehicles has a higher probability to be involved in a severe crash in model-B.

Model-C is the LV vs. LV crash type model and the results of this model indicates four significant factors contributing to the crash injury severity binary outcome. These factors were; posted speed limit, rural vs. urban areas, lighting conditions, and the intersection relation of the crash. The effects of these variables can be explained in the exact same way with the model-A and model-B results.

Although, all the variables were used in all three of the models, the significant factors for each model have dissimilarities. The differences among three models in terms of significant factors and their effect on the models are summarized in Table 21. As it is seen in the table, posted speed limit, lighting
condition, and intersection variables are affecting the injury severity positively and rural areas are more likely to have severe crashes in all three models. DUI, more than two vehicles, and shoulder have positive effect on crash injury severity outcome in model-A and model-B. Off roadway crashes are more likely to be severe in model-A while on roadway crashes are riskier in model-B. Owner is driver factor has significant positive effect on model-A, and a significant negative effect on model-B. Blacktop-concrete and road surface condition variables are only significant with a negative effect on the injury severity binary outcome of model-A. To sum up, it is distinguished that LV vs. LV crashes have the smallest number of contributing factors to the crash injury severity while PV vs. PV crashes have the largest number of predictor variables.

In this chapter five different models and their results were discussed and presented as well as comparisons between/among some of them. The overall summary and conclusion of the thesis will be given in the next chapter.
CHAPTER SEVEN: CONCLUSIONS

The main objectives of this study were to investigate the characteristics of large vehicle crashes in order to identify the contributing factors to injury severity levels. Severe is considered as incapacitating and fatal. Large vehicles are considered as: heavy trucks, truck-tractors, RVs, buses with 9-15 seats, and buses with over 15 seats.

To achieve this purpose, three different statistical approaches were proposed. First the descriptive statistics, second is the binary logistic regression modeling, and third is the CHAID decision tree modeling.

Descriptive statistics were examined to get the distribution of severe crashes / fatal crashes for LV-PV (LV vs. PV crashes) and PV-PV groups through various factors which were addressed by researchers. In this part, crash severity level, environmental conditions, large vehicle involvement, passenger vehicle involvement, motorcycle involvement, bike / pedestrian involvement, and driver characteristics (i.e. DUI, residence etc.) were discussed for both crash groups.

The main results are:

(1) Non-LV involved crashes are more likely to have incapacitating injuries than LV involved ones; however, the fatality rate is significantly high in LV involved crashes.

(2) There are several factors (i.e. lighting conditions, DUI) influencing the injury severity of PV vs. PV, LV vs. PV, and LV vs. LV crashes. The bad lighting
conditions, high speed limits, no-shoulder roadways, driving under the influence of alcohol or drugs, intersections, blacktop road surface, rural areas, and multiple vehicle pile-ups prove to have positive affect on the injury severity in all three crash groups.

Analyzing crash severity by type of vehicle is considered crucial criteria not only because it reflects the importance and danger of large vehicle crashes but also because it reveals differences between a large vehicle crash and smaller vehicle crash. Crash severity is affected by various factors including driver characteristics, vehicle characteristics, environmental factors, and roadway features.

Fully understanding the impacts that these factors worsen the crash severity is beneficial for selecting proper countermeasures to reduce the crash severity of large vehicle crashes. Furthermore, this insight can help identify solutions for decreasing the severity and fatality rates of crashes.

A logistic regression binary output was used to estimate the crash severity models for large vehicle involved crashes. According to the results of crash injury severity modeling and the analysis of LV involved crashes, some conclusions can be given:

1) Residence of the driver, owner is driver (Zhu and Srinivasan in 2011 supports this result), number of vehicles involved, lighting condition, alcohol/drug use of drivers, roadway section with/without shoulder, rural or urban area,
blacktop/concrete road surface type, on/off roadway, intersection related/not related site location, posted speed limit, whether a bus or truck was involved, and different vehicle types appear as the main influence to large vehicle crash severity. Findings of Lemp et al. (2011) strengthens the results in this model.

(2) The factors of resident drivers, non-owner drivers, more than two vehicle crashes, non-bright light condition, DUI drivers, roads without shoulder, urban, blacktop surface type, on roadway crashes, intersection related locations, higher speed limit, and truck involved crashes are more likely to reduce the severity of LV involved crashes. The crash type variable findings indicate that LV vs. LV crashes were more likely to be severe when compared to LV vs. PV and single LV crashes. Furthermore, the LV vs. motorcycle and LV vs. bike/ped/moped crashes have more probability to be severe crashes.

(3) Non-owner drivers could induce LV crash severity. The reason may be that most drivers of LV’s are not owners of the truck or buses, because those vehicles are more likely to be commercial vehicles.

(4) Drivers who are Florida residents are more likely to be involved in severe crashes. This finding could be explained as the unfamiliar drivers with the roadways drive more careful.

(5) Based on the magnitudes of the variable coefficients, the variables of maximum speed limit, number of vehicles involved, and the type of crash all have a major impact on the crash severity level. Thus proving the restriction to driving
speed as a principle factor for the safety of LV’s and vehicles involved in a crash with LV’s.

Furthermore, a CHAID decision tree model is also conducted to the LV involved crashes dataset. According to the results of CHAID:

(1) There are seven variables which came out to be significant. The importance of the variables for severity is respectively: posted speed limit, Involved vehicle type, Number of vehicles involved, DUI, Lighting conditions, Rural or urban, and Intersection relation of the crashes. Chang and Chien (2013) also found similar factors affecting the large truck crash severity with non-parametric models.

(2) The decision tree indicates 14 terminal nodes of different crash scenarios based on the contributing factors, with their probabilities to be severe crashes.

A comparison of the two models mentioned above has also been provided. The comparison results indicated that the regression and CHAID decision tree models are comparable.

A modeling structure is also built in order to analyze the PV (personal vehicle) vs. LV (large vehicle) crashes, LV vs. LV crashes, and PV vs. PV crashes. The main benefit of this modeling structure is its ability to show three different small and large vehicle crash combinations at the same time, and compare the results of them. Binary logit modeling procedure has been used for those three models. The main results of the modeling structure are:
(1) Higher speed limits, non-bright lighting conditions, rural areas, and intersection related factors are reducing the likelihood of severity in LV vs. LV crashes. Findings in this model are also consistent with Khorashadi et al. (2005)’s study.

(2) In addition to the contributing factors in model-A, LV vs. PV crashes severity is positively affected by DUI drivers, more than two vehicles involvement, and no shoulder factors. Owner is driver and, on/off roadway variables have negative effect in this model.

(3) The PV vs. PV crashes crash severity is influenced by two more factors compared to the model-B. These factors are blacktop surface of roadway and bad road surface conditions. The owner is driver and on/off roadway variables have opposite effects on severity in contrast model-B.

Based on these statistical analyses for large vehicle involved crashes, several countermeasures can be suggested:

(1) The maximum speed limits for large vehicles should be reduced in order to control the severe crashes occurring due to high speed limits. Speed limit signs could also be adjusted. Some dynamic signs such as changeable message signs with radar and speed feedback signs could be effective to reduce driver speed.

(2) Lighting conditions should be improved. Streetlights at all types of roadways should also be revised and be opened even in sunrise and sunset times.
(3) Intersections are also important site locations in terms of crash severity. So, intersection safety improvements are also needed to reduce the LV involved severe crashes in particular.

The limitation in this study was the use of one year data from the state of Florida. However, the crash data from the state of Florida may not represent the entire nations’ crash characteristics. Thus, it is recommended that in the future studies, several years of crash data from different regions be used.

This study analyzed the crash injury severity considering the dimensions of vehicles. The importance of vehicle sizes should be further studied to include different crash scenarios such as; different type of vehicles involvement, crash types, and more site locations. Furthermore, interactions among various variables such as gender and ages of the drivers could be used.
