This Patent is brought to you for free and open access by the Technology Transfer at STARS. It has been accepted for inclusion in UCF Patents by an authorized administrator of STARS. For more information, please contact lee.dotson@ucf.edu.
Methods, devices and systems for generating ultrashort optical linear chirped pulses with very high power by amplifying the pulses so that their temporal duration is longer than the storage time of the amplifying medium. The additional gain factor is related to the ratio of the storage time to the stretched pulse. A preferred embodiment connects a mode locked laser source that generates optical pulses whose duration is stretched with a chirped fiber Bragg grating. Embodiments include methods, devices and systems causing an extreme chirped pulse amplifier (XCPA) effect in an oscillator.

EXTREME CHIRPED/STRETCHED PULSED AMPLIFICATION AND LASER

This is a Divisional of application Ser. No. 10/828,965 filed Apr. 21, 2004 now U.S. Pat. No. 7,095,772 which claims priority of U.S. Provisional Application 60/472,383 filed May 21, 2003.

FIELD OF USE

This invention relates to lasers, in particular to methods, devices and systems for generating ultra-short optical pulses with very high power by stretching optical pulses to durations longer than the energy storage time of an optical amplifier, and for deployment of an extreme chirped pulse amplification (XCPA) effect in an laser oscillator and an external amplification.

BACKGROUND AND PRIOR ART

Semiconductor gain mediums have a short energy storage lifetime which makes energy extraction from the semiconductor gain medium less efficient compared with other gain mediums that have a longer energy storage lifetime. That is, a semiconductor optical amplifier is easily saturated and, after reaching the saturation regime, energy extraction from the semiconductor optical amplifier is dramatically decreased. It is well known that semiconductor optical amplifiers are not a proper optical amplifier for high power generation.

Previously, external cavity mode-locked semiconductor laser oscillators did not use dispersion management schemes that provide breathing mode operation. In non-breathing modes of operation, laser pulse time duration is similar at all cavity points. However, the preferable pulse duration, prior to the saturable absorber, is much shorter than pulse duration passing through the semiconductor gain media. Short pulses below ~1 ps. bleach the saturable absorber much easier, but such short pulses would initiate different ultra-fast dynamic processes in gain media which are detrimental for the laser operation—the gain would be decreased and the pulse would be strongly nonlinearly chirped. The nonlinear chirp is very difficult to compensate and generate in the end ultrashort pulses.

SUMMARY OF THE INVENTION

A primary objective of the present invention is to provide methods, devices and systems for generating stretched, linearly chirped optical pulses with high power from the all-semiconductor laser oscillator that could be efficiently externally compressed to approximately 200 fs. This is achieved in the breathing mode operation of laser oscillator by stretching time duration of the pulses passing the gain media, to suppress self-phase modulation, and compressing it subsequently prior to the saturable absorber.

A secondary objective of the present invention is to provide methods, devices and systems for generating ultra-short optical pulses with very high power by increasing the temporal duration of the pulses passing the gain media to be longer than the storage time of amplifying medium. If the time duration of the optical pulse is longer than the energy storage lifetime, then the energy extraction from semiconductor gain medium is not limited by the energy storage lifetime of the semiconductor optical amplifier but by continuous saturation power multiplied by the time duration of optical pulse. This is done by an extreme chirped pulse amplification technique using chirped fiber Bragg grating.

A third objective of the present invention is to provide methods, devices, and systems to deploy an extreme chirped pulse amplification (XCPA) effect in a laser oscillator and to generate extremely linearly chirped high-power pulses externally compressible to approximately 200 fs.

Preferred embodiments methods and systems of generating ultrashort optical pulses having increased optical power can include generating optical pulses from a source, such as a modelocked laser source, stretching duration of each of the optical pulses to be greater than energy storage time of an optical amplifier, amplifying the stretched optical pulse with the optical amplifier, and compressing the optical pulse, wherein optical power of the compressed optical pulse can be increased at least approximately 100 times.

The optical pulses can be linear chirped pulses. The modelocked laser source can be a gain-flattened mode-locked laser source, and the optical amplifier can be a semiconductor optical amplifier, such as a grating coupled surface emitting optical amplifier.

Preferred embodiments of an extreme chirped pulse amplifier (XCPA), can include methods, systems and devices for generating optical pulses, stretching temporal duration of the optical pulses to be greater than storage time of an amplifying medium, amplifying the stretched optical pulses, and compressing the stretched optical pulse, wherein higher power optical pulses are generated.

Additional preferred embodiments and systems of generating ultrashort optical pulses having increased optical power can include generating optical pulses with high optical energy and a linear chirp, stretching the duration of each optical pulse to be greater than the energy storage time of an optical amplifier, amplifying the stretched optical pulse with said optical amplifier, compressing the optical pulse, wherein the optical power of compressed optical pulse is increased.

The embodiments can include modulating the optical pulse whereby the optical pulse is further shortened, by using an active modulator such as a LiNbO3 modulator. Modulating can also include a passive modulator such as a multiple quantum well saturable absorber.

The embodiments can further route the compressed optical pulse back to the generating step, and output coupling the compressed optical pulse by an fiber coupler.

Additional preferred embodiments of an extreme chirped pulse amplifier (XCPA) laser can include methods, systems and devices for generating optical pulses, stretching temporal duration of the optical pulses to be greater than storage time of an amplifying medium, compressing the stretched optical pulses and amplifying the compressed optical pulses, wherein higher power optical pulses are generated.

The optical pulses can be generated by a gain-flattened mode-locked laser source. Stretching can include a chirped fiber Bragg grating. Compressing can include a dual pass grating compressor.

The embodiments can include modulating the optical pulse wherein the pulse is further shortened, by using an active modulator such as a LiNbO3 modulator. Modulating can also include a passive modulator such as a multiple quantum well saturable absorber.

The optical pulses can be generated by a gain-flattened mode locked laser source, and the stretching and compressing can include a chirped fiber Bragg grating.

Further objects and advantages of this invention will be apparent from the following detailed description of the presently preferred embodiments which are illustrated schematically in the accompanying drawings.
BRIEF DESCRIPTION OF THE FIGURES

The present invention is not limited in its application to the details of the particular arrangements shown since the invention is capable of other embodiments. Also, the terminology used herein is for the purpose of description and not of limitation.

FIG. 1a shows a setup of a preferred embodiment of the extreme chirped pulsed amplifier (X-CPA) invention.

**DESCRIPTION OF THE PREFERRED EMBODIMENTS**

Before explaining the disclosed embodiments of the present invention in detail it is to be understood that the invention is not limited in its application to the details of the particular arrangements shown since the invention is capable of other embodiments. Also, the terminology used herein is for the purpose of description and not of limitation.

FIG. 1a shows a setup of a preferred embodiment of the extreme chirped pulsed amplifier (X-CPA) invention.

Mode-locked laser 110 with semiconductor gain medium is used as an oscillator. The repetition rate of the oscillator is adjustable. Optical isolator (OI) 120, 140 allows the optical pulse to travel in the direction of the arrow and blocks the optical pulse in the reverse direction. Preampifier 130 is a semiconductor optical amplifier that (a) compensates for losses from the first optical isolator 120, the optical circulator 150, and the Chirped Bragg grating 160; (b) develops more power to saturate the amplifier 170; and (c) adjusts the optical pulse repetition rate. Optical circulator (OCIR) 150, 180 is a component that transmits an incoming pulse from port 1 to port 2 while transmitting a second incoming pulse from port 2 to port 3 as illustrated by the arrows in FIG. 1b. The first chirped fiber Bragg grating (CFBG) 160 is used to stretch the optical pulse and the second chirped fiber Bragg grating (CFBG) 190 is used to compress the optical pulse. Amplifier 170 is a semiconductor optical amplifier for high power generation.

By stretching the time duration of the optical pulse duration such that it is longer than the energy storage lifetime of the semiconductor gain medium, the energy extraction from the semiconductor gain medium is not limited by the energy storage lifetime of semiconductor optical amplifier but by continuous saturation power multiplied by the time duration of optical pulse. In the preferred embodiment, chirped fiber Bragg grating 160, 190 provides dispersion of approximately 2000 ps/nm so that an approximate 8 nm pulse was stretched to approximately 16 ns. The recombination lifetime (energy storage lifetime) of the semiconductor gain medium of amplifier 170 can be less than approximately 1 ns.

FIG. 2 is a chart showing the preferred components used for chirped pulse amplification and the advantages as to their use for the setup of FIG. 1a.

**GFMLL Oscillator**

FIG. 3 is a preferred embodiment of the oscillator 300 for the X-CPA invention. The oscillator is a gain-flattened mode-locked laser (GFMLL) where characteristics are such that (1) amplitude, phase, and optical spectrum bandwidth can be manipulated using a Fourier plane inside the cavity and (2) active, passive, and hybrid mode-locking techniques are possible.

The oscillator is comprised of the first high reflector (HR) 305 and second high reflector 330 that are mirrors that exhibit high reflectance at the operating wavelength of the oscillator. The band pass filter (BPF) 310 allows the optical spectrum bandwidth of the oscillator to be changed. The gain flattening filter (GFF) 315 allows the amplitude of the optical spectrum to be modified. The first lens 320 and the diffraction grating (DG) 325 form the Fourier plane inside the cavity of oscillator 300. The second lens 335 and the third lens 345 collimate the beam to and from the semiconductor optical amplifier (SOAs) 340. The aperture 350 provides for selection of the spatial beam profile. The output coupler 360 couples the mode-locked pulse train out from the oscillator. The fourth lens 355 and the fifth lens 365 provide for stabilization of the cavity.

FIG. 4a shows the optical spectrum bandwidth of the GFMLL oscillator 300 of FIG. 3 operating in active mode-lock at an approximately 200 MHz repetition rate. Optical bandwidth is approximately 11.4 nm in the range from approximately 961.8 to approximately 973.2 nm. FIG. 4b shows the mode-locked output pulse shape of the GFMLL oscillator 300 in the time domain as measured by a fast photo-detector and a digital sampling oscilloscope.

FIG. 5a shows the bandwidth of the GFMLL oscillator 300 of FIG. 3 with the Fourier plane manipulated to produce...
optical characteristics different from that of the prior example. The optical bandwidth is adjusted to approximately 7.8 nm in the range from approximately 971.1 to approximately 978.9 nm with the optical power spectrum equalized to an average power of approximately 15.2 mW. Energy per pulse was approximately 45 pJ. The optical spectrum is adjusted to match the reflection bandwidth of the diffraction grating 325. FIG. 5b shows the mode-locked output pulse shape of the GFML oscillator 300 in the time domain as measured by a fast photo-detector and a digital sampling oscilloscope. Pulse width is approximately 189 ps.

Active mode-locking for the GFML oscillator 300 is achieved by way of gain modulation. Spectrum modulation is achieved by way of the fourier plane inside the cavity. Homogeneous spectrum narrowing is prevented by using a gain flattening filter.

Stretcher and Compressor

FIGS. 6a and 6b show the reflectance spectrum of the chirped fiber Bragg grating (CFBG) 160, 190 of FIG. 1 used for dispersion of the optical pulse. FIG. 6a shows the optical spectrum of the reflection 610 from the first chirped fiber Bragg grating 160 with a negative dispersion. FIG. 6a also shows the optical spectrum of the reflection 620 from the second chirped fiber Bragg grating 190 with a positive dispersion. The reflectance bandwidth for both the compressor CFBG 160 and the stretcher CFBG 190 is approximately 8 nm in the range from approximately 971 nm to approximately 978 nm and the spectrum exhibits a nice flat reflectance. FIG. 6b shows the group delays 630, 640 of the two CFBG 160, 190 used as a stretcher and a compressor to be approximately 2000 ps/nm each. This means an approximately 8 nm bandwidth optical pulse can be stretched to approximately 16 ns.

FIG. 7a shows the reflected optical spectrum for the stretcher CFBG 160 mapped onto the streak camera image for 7b of the optical pulses from the stretcher CFBG 160. FIG. 7c shows the reflected optical spectrum for the compressor CFBG 190 mapped onto the streak camera image FIG. 7d of the optical pulses for the compressor CFBG 190. For both FIGS. 7c and 7d, the vertical axis of the streak camera image represents time and the horizontal axis of the streak camera image represents wavelength. In both images, each optical pulse has a bandwidth of approximately 8 nm and is stretched approximately 16 ns.

FIGS. 8a to 8c show streak camera images of the optical pulse at three different points in the extreme chirped pulsed amplifier (X-CPA) invention, 100. FIG. 8a shows the optical pulse train as output from the oscillator 110, with an approximately 8 nm optical spectrum bandwidth and a pulse repetition rate of approximately 5 ns. FIG. 8b shows the optical pulse stretched to approximately 16 ns from the stretcher CFBG 160. FIG. 8c shows the optical pulse compressed from the compressor CFBG 190. For FIGS. 8a to 8c, the vertical axis of the streak camera image represents time and the horizontal axis of the streak camera image represents wavelength.

FIG. 9 shows the normalized optical power spectra at three different points in the extreme chirped pulsed amplifier (X-CPA) invention, 100. The optical spectrum 910 is measured at the output of the preamplifier 130, the optical spectrum 920 is measured at the output of the amplifier 170, and the optical spectrum 930 is measured at the output of the compressor CFBG 190. Optical power spectra are nearly flat in all instances.

Preamplifier and Pulse Selection

FIG. 10 shows a schematic representation of the Gain Flattened Mode-Locked Laser 300 followed by the preamplifier and pulse picker 1000. The preamplifier/pulse picker stage is comprised of a first lens 1010, a semiconductor optical amplifier (SOA) 1020, and a second lens 1030. Modulation 1050 of the SOA 1020 provides amplification and pulse selection of the optical pulse train 1040 from the GFML oscillator 300.

FIG. 11a shows the mode-locked output pulse shape of the GFML oscillator 300 in the time domain as measured by a fast photo-detector and a digital sampling oscilloscope. The repetition rate of the oscillator is 200 MHz. FIG. 11b shows a streak camera image (20 ns time window) of the stretched pulse from the GFML oscillator 300. FIG. 11b has been stretched in the vertical axis to show that optical pulses overlap so that there are approximately four pulses at the same moment as indicated by the horizontal line 1100. Pulse overlap is indicative of inefficient energy sharing between pulses.

FIG. 12a shows the mode-locked output pulse shape after the preamplifier stage 1000 in the time domain as measured by a fast photo-detector and a digital sampling oscilloscope. The output pulse train 1060 of the preamplifier stage 1000 has been amplified and pulses selected so that the resulting frequency is 50 MHz. FIG. 12b shows a streak camera image (100 ns time window) of the stretched pulse from the preamplifier stage 1000. Temporal pulse overlap has been eliminated by the pulse biased preamplifier stage 1000.

Semiconductor Optical Amplifier

The semiconductor optical amplifier of the preamplifier stage 1000 and the amplifier 170 is an approximately 980 nm InGaAs Quantum Well structure that is an angled stripe inverse bow-tie gain guide amplifier. The angled stripe provides low reflectivity. The structure is a low loss that is good for high power generation and provides a good spatial mode profile. The amplifier provides large gain volume and adiabatic beam expansion.

Concept Verification

FIGS. 13 and 14 are schematic representations of the experimental setup to verify the concept of the X-CPA invention using a semiconductor gain medium. FIG. 13 demonstrates the amount of gain saturation without pulse stretching and is comprised of GFML 1310, optical isolator 1320, and amplifier 1330. Amplifier 1330 is further comprised of the first lens 1340, the SOA 1350, and the second lens 1360.

FIG. 14 demonstrates the amount of gain saturation with pulse stretching and is comprised of GFML 1410, first optical isolator 1415, preamplifier 1420, the second optical isolator 1440, optical fiber as an optical pulse stretcher 1445, and amplifier 1450. The preamplifier 1420 is further comprised of the first lens 1425, the first SOA 1430, and the second lens 1435. The amplifier 1450 is further comprised of the third lens 1455, the second SOA 1460, and the fourth lens 1465.

FIGS. 15a through 15f show the experimental results of the gain saturation of the experimental setups of FIGS. 13 and 14. FIG. 15a shows the optical power spectrum of the GFML oscillator 1410 with FWHM pulse width of approximately 11.4 nm and an average power of approximately 3 mW. FIG. 15b shows the mode-locked output pulse shape of the GFML oscillator with pulse duration of approximately 96.4 ps. FIG. 15c is a streak camera image of the pulse at the output of the GFML 1410 showing no pulse stretching. FIG. 15d is a streak camera image of the stretched pulse after fiber spool...
1445 that provides pulse stretching. The pulse is stretched to approximately 2.96 ns and corresponds to approximately -64.9 ps/km/nm.

FIGS. 16a, 16b, 17a, and 17b show experimental measurements of gain saturation determined from the experimental setups of FIGS. 13 and 14. FIG. 16a shows output power vs. input power with an unstretched pulse of approximately 100 ps. The square data points 1610 represent data for an injected current of approximately 250 mA. The circular data points 1620 represent data for an injected current of approximately 500 mA. The triangular data points 1630 represent data for an injected current of approximately 750 mA. FIG. 16b shows gain vs. input power with an unstretched pulse of approximately 100 ps, in length. The square data points 1640 represent data for an injected current of approximately 250 mA. The circular data points 1650 represent data for an injected current of approximately 500 mA. The triangular data points 1660 represent data for an injected current of approximately 750 mA. FIG. 16b shows decreasing gain with output power indicating saturation.

FIG. 17a shows output power vs. input power with a stretched pulse of approximately 3 ns. The square data points 1710 represent data for an injected current of approximately 250 mA. The circular data points 1720 represent data for an injected current of approximately 500 mA. The triangular data points 1730 represent data for an injected current of approximately 750 mA. FIG. 17b shows gain vs. input power with a stretched pulse of approximately 3 ns, in length. The square data points 1740 represent data for an injected current of approximately 250 mA. The circular data points 1750 represent data for an injected current of approximately 500 mA. The triangular data points 1760 represent data for an injected current of approximately 750 mA. FIG. 17b shows no saturation behavior of the output power so that energy extraction through the XCPA will be improved.

X-CPA System Experimental Results

FIG. 18a shows a schematic view of the experimental set-up 1800 for the X-CPA invention. The GFMLL 1810 generates a 200 MHz mode-locked pulse fed to preamplifier 1815 that amplifies and selects pulses from the optical pulse train so that the output pulse rate is approximately 50 MHz. The optical pulse is stretched by way of the CFBG 1830 and sent to the amplifier 1845. The optical pulse is further amplified by amplifier 1845 and sent to a second amplifier 1850. The second amplifier 1850 is pulse biased with 100 ns electrical pulse at 10 kHz repetition rate in order to avoid a thermal management due to high current injection. FIG. 18b shows the operating parameters for the experimental set-up 2000 of FIG. 19a. The GFMLL oscillator 2010 generates a 200 MHz mode-locked pulse fed via a first Faraday isolator 2015 to pulse-picker 2020 that selects pulses from the optical pulse train so that the output pulse rate is approximately 50 MHz and provides approximately 8.4 dB gain. The optical pulse is passed through the second Faraday isolator 2040 and further amplified by the first amplifier 2045 with approximate gain of 9.9 dB, passed through a third Faraday isolator 2050 and provided to a second amplifier 2055. The second amplifier 2050 is pulse biased with 100 ns electrical pulse at 10 kHz repetition rate in order to avoid a thermal management due to high current injection. Total gain through the system 2000 is approximately 33.3 dB.

FIG. 20c shows two optical spectrum curves of final amplifier before and after signal injection. When a signal is injected into final amplifier, the strong ASE suppression due to gain saturation is occurred.

Simulation Sequence

FIG. 21 is a preferred embodiment of the simulation sequence flow chart for the invention. FIG. 21 explains the effect of the X-CPA in terms of stretched pulse widths. The energy extraction efficiency between unstretched and stretched pulse is simulated using dynamic semiconductor laser rate equations.

For simulation, the oscillator was selected to have parameters of input energy from approximately 0.1 µJ to approximately 1 nJ and a transform-limited Gaussian input pulse with an approximately 1 nm to approximately 5 nm spectrum bandwidth. The amplifier was selected to have saturation energy of approximately 0.1 µJ, carrier lifetime of approximately 200 ps, line-width enhancement factor of approximately 3, and small signal gain of approximately 30 dB. CFBG constants of both approximately 87.5 ps/nm and approximately 1000 ps/nm dispersion, each with an approximately 1 nm and 5 nm optical spectrum bandwidth, were selected for the simulation.

FIGS. 22a and 22b are graphs of the simulation results (gain characteristics) of the invention. The simulation results show how stretching (the basic concept of X-CPA) influences energy extraction efficiency (i.e. extracted gain) in terms of stretched pulse width.

FIG. 22a shows the simulation results of an approximate 1 nm transform limited (TL'd) pulse with gain shown on the vertical axis and normalized saturation level Ein/Esat shown on the horizontal axis. The rectangular data points 2310 represent the unstretched pulse. The circular data points 2320 represent the stretched pulse using the CFBG with an approximately 87.5 ps/nm stretching/compression and approximately 8 nm optical spectrum bandwidth resulting in a pulse length of approximately 87.5 ps. The triangular circular data points 2330 represent the stretched pulse using the CFBG with approximately 2000 ps/nm stretching/compres-
sion and an approximately 1 nm optical spectrum bandwidth resulting in a pulse length of approximately 2000 ps.

FIG. 226 shows the simulation results of a 5 nm transform limited (TL'd) pulse with gain shown on the vertical axis and normalized saturation level $E_{in}/E_{sat}$ shown on the horizontal axis. The rectangular data points 2240 represent the unstretched pulse. The circular data points 2250 represent the stretched pulse using the CFBG with an approximately 700 ps/nm stretching/compression and approximately 5 nm optical spectrum bandwidth resulting in a pulse length of approximately 437.5 ps. The triangular circular data points 2260 represent the stretched pulse using the CFBG with approximately 2000 ps/nm stretching/compression and an approximately 5 nm optical spectrum bandwidth resulting in a pulse length of approximately 10,000 ps.

The results show the gain difference between a 1 nm and 5 nm transform-limited pulse laser with the CFBG of approximately 2000 ps/nm stretching/compression. The simulation results also show that the gain difference between amplification without and with the CFBG of approximately 2000 ps/nm stretching/compression and approximately 8 nm optical spectrum bandwidth is greater than approximately 15 dB with approximately 1 nJ input energy for an approximately 5 nm TL'd pulse.

Breathing MLL with Modulator

FIG. 23 shows a compact "Breathing Mode" Mode locked laser (MLL) embodiment 2300 with a modulator 2350. The laser is comprised of fiber components such as the SOA 2310, the output coupler 2320, the first optical circulator 2330, first CFBG (stretcher) 2380, the modulator 2350, the second optical circulator 2370, and the second CFBG (compressor) 2340. Instead of free space bulk diffraction gratings as a pulse stretcher and a pulse compressor (FIG. 24), two CFBGs are put inside cavity to make a laser compact; first CFBG 2380 is a stretcher and second CFBG 2340 is a compressor. The time duration of stretched pulse before SOA 2310 is much longer than energy storage time of SOA 2310. Therefore nonlinearity i.e. self-phase modulation which can distort an optical pulse can be reduced and at the same time optical pulse can extract more energy that stored energy inside SOA 2310. After SOA 2310, optical pulse is divided by output coupler 2320. Optical pulse which remains inside cavity is compressed by a CFBG stretcher 2340 and then it goes through a modulator 2350 that has a short gating time. The modulator 2350 can be a passive MQW SA or LiNbO3 intensity modulator.

Dispersion-Managed Breathing Mode-Locked Semicon­ductor Ring Laser

FIGS. 24a to 24c show an experimental set-up 2400 for the dispersion managed breathing-mode $\alpha$-ring cavity diode laser. FIG. 24a shows the mode-locked semiconductor $\alpha$-ring cavity 2402. FIG. 24b shows the setup for diagnostics measurement of spectra and autocorrelations 2404. FIG. 24c shows the setup 2450 used for dispersion element 1 (compressor) 2416, dispersion element 2 (stretcher) 2420, and the external compressor 2435.

The salient feature is the incorporation of the compressor 2416 and stretcher 2420 in the sigma cavity. An optical isolator 2413, such as a commercial product from Electro-Optics Technology with isolation >30 dB, permits light propagation only in the counterclockwise direction inside the cavity. Since the saturable absorber (SA) 2428 is designed for normal incidence, $\alpha$-shape ring propagation is managed with an optical circulator comprising half-wave plate 2418, quarter-wave plate 2426, and a polarizing beam-splitter (PBS) 2419. FIG. 24a shows the external compressor 2435, dispersion element 1, 2416, and dispersion element 2, 2420 are standard dual pass grating compressors 2451, 2454, (we used commercial Spectrogon gratings with 1800 lines per mm), with internal telescopes, hence they can operate as pulse compressors or stretchers. The introduced dispersion amounts of those components were controlled by the relative position between gratings. Output ports 2414, 2424 are after the gain medium 2410 and after the SA 2428. Both intracavity diode 2410 and external cavity semiconductor optical amplifier (SOA) 2432 are angle-stripe, approximately 0.5 mm long SOAs. The chirped SA 2428 has multiple quantum wells with thickness of approximately 70/75/80 A to sustain broad bandwidth saturable absorption. Passive mode locking is established using the SA 2428 and a dc-biased (approximately 190 mA) intracavity SOA 2410. The sigma cavity laser outputs 2415, 2425 are individually directed to a spectrometer 2430, such as a commercial Jarell Ash equipped with a Reticon CCD camera, or to an external SOA 2432 to boost the power prior to the autocorrelator 2436, such as a commercial Femtocyte FR-103.

The pulse train repetition rate is approximately 1.16 GHz, corresponding to the 31st harmonic of the laser cavity. The pulse spectrum after the SA 2428 is recorded from output 2425 while keeping the introduced dispersion by element 2 2420 constant and varying the dispersion introduced by element 1 2416 and is shown in FIG. 25. A fixed dispersion of approximately 4.57 ps/nm is introduced by element 1 2420. In each dispersion element, a 1 cm grating position variation corresponds to an introduced dispersion of approximately 0.83 ps/nm. There is an optimal grating position in element 1 2416, which introduces approximately -0.25 ps/nm additional dispersion than that introduced by element 2 2420. When such optimal dispersion is introduced, the obtained spectrum is the broadest and pulses are compressible to their shortest duration. The optimal total dispersion of approximately -0.25 ps/nm introduced by elements 1 2416 and 2 2420 compensates the dispersion of other cavity elements. Small variations in the total cavity dispersion cause dramatic changes in the spectral shape and width.

FIG. 26 displays measurements after the gain element 2410 from output 1 2415 of the second harmonic intensity autocorrelation versus dispersion introduced by elements 1 2416 and 2 2420. Data points are collected for movable grating position adjustments of approximately 1 cm yielding approximately 200 data points and the map is obtained by interpolation. On-diagonal map values occur for dispersions of equal magnitude and opposite sign in elements 1 2416 and 2 2420. From the map we can see that when the laser operates in the regime near the diagonal region of the map, output pulses were shorter without coherent spikes. In contrast, noise bursts—temporally broad pulses with coherence spikes—were observed for off-diagonal map values.

FIG. 27 illustrates similar measurement after the SA 2428 from output 2 2425 of spectral bandwidth (FWHM) versus dispersion in elements 1 2416 and 2 2420. The bandwidth is slightly broader close to the map diagonal. The results along the diagonal of the map are summarized in FIG. 28. Externally compressed pulse autocorrelation and bandwidth are plotted versus dispersion introduced by element 2 2420. A threshold value for the dispersion occurs at approximately -3.3 and approximately 4.3 ps/nm for dispersion elements 1 2416 and 2 2420, respectively. Beyond this threshold, the spectrum broadens more than twice, output pulses are externally compressible below approximately 1 ps and the laser is operating in breathing mode. The breathing mode means that
with each cavity round-trip, the pulse is stretched when passing through the gain medium 2410 and compressed when incident on the SA 2428.

FIGS. 29a and 29b show a cross-correlation measurement set-up. FIG. 29a shows a hybridly mode-locked α-cavity laser 2902 with four outputs 2915, 2922, 2930, 2932, for pulse evolution characterization. FIG. 29b shows the set-up 2904 for measurements of spectra as well as autocorrelation and cross-correlation traces. The intracavity SOA 2910 was biased with approximately 92 mA of DC and a superimposed radio frequency (RF) signal modulated the gain at approximately 323 MHz. Introduced dispersions were approximately ~5 ps/nm in the element 1 (compressor) 2916 and approximately +5 ps/nm in element 2 (stretcher) 2930. As depicted in FIG. 29a, the signals from the four different cavity ports 2940 are split after the SOA amplifier 2943 with a 50/50 beam splitter 2946. Half of the beam is guided through the delay line 2950 and then recombined with the other half which passes through the external compressor 2947. The pulse from the cavity is combined with a compressed version of itself, and the autocorrelator 2960 signal reveals the two-pulse autocorrelation trace. The side pulse on the trace represents the cross-correlation of the two versions of the pulse. When the compressed version is much shorter than the original (in this case it is more than approximately 40 times shorter), the cross-correlation trace measures the temporal profile of original pulse intensity.

FIGS. 30a, 30b, 30c, 30d shows the optical power spectra from the four key points of the cavity—after the gain media (intracavity SOA) output 2915, before the SA output 2930, after the SA output 2932, and before entering back to the gain media output 2922. Spectra of the pulse propagating through the laser cavity are similar in shape, with the peak around the same wavelength.

FIGS. 31a, 31b, 31c, 31d shows the cross-correlation traces from the four laser cavity outputs. The stretched pulses exhibit an asymmetric temporal profile with a steep leading edge and a long decaying trailing edge. The stretched pulse traces FIG. 31a and FIG. 31d also contain an artifact from the autocorrelation. The dashed line depicts how the contributions from autocorrelation and the cross-correlation overlap. The cross-correlation traces from before and after the SA in FIG. 31a and FIG. 31c are similar to autocorrelation traces, since those are already short pulses in the cavity and were not externally compressible. The stretched pulse before and after the gain media is more than approximately 20 times broader than compressed one before and after the SA. This measured pulse duration change while propagating in the cavity demonstrates that laser operates in the breathing mode. The pulse energy after the cavity gain media is more than approximately 100 times higher than before the gain media as shown in FIG. 31a and FIG. 31d. This verifies that intracavity chirped pulse amplification was achieved.

Dispersion-Managed Breathing Mode-Locked Semiconductor Ring Laser Numerical Simulation

FIG. 32 is a flow diagram representing the algorithm to simulate the laser pulse formation from random noise input in the dispersion-managed breathing mode-locked semiconductor ring laser of FIG. 24e. Elements of the Split-Step Fourier algorithm are arranged in an order analogous to the semiconductor ring laser. The constants used in the simulations are listed in the table of FIG. 33. A frequency filter with FWHM equal to approximately 7.6 nm accounts for the finite bandwidth of the SA and the semiconductor gain. A time filter with FWHM equal to approximately 131 ps, represents a RF modulation of the SOA as a gain element. The results from the simulations are scaled to the measured pulse energies after the cavity gain element energy is equal to approximately 35 pJ and after the SA energy is equal to 0.86 pJ. The pulse energy after the gain is approximately 1.64 times larger than the gain saturation energy and the pulse energy after the SA is approximately 2.8 times larger than the saturation energy of the SA.

The mode-locked stretched pulse formation from input random noise is shown in FIG. 34. The steady-state pulse shape is formed after approximately 350 cavity round trips.

FIGS. 35 and 36 show the build-up of the mode-locked spectra after the cavity gain element and after the SA. The steady-state pulse spectral and temporal intensity after approximately 600 simulated cavity round trips are compared with the measured ones as shown in FIGS. 37a, 37b, 37c and 37d. The main part of the simulated stretch pulse fit well as compared to the experimentally measured pulse. The leading part of the cross-correlation trace of FIG. 37c contains an artifact from the middle autocorrelation trace of FIG. 31a which enhances the leading and trailing edge of the pulse measured by the two-pulse autocorrelation technique.

In FIG. 37d the steady-state simulated compressed pulse temporal intensity after the SA is compared with the corresponding pulse retrieved by the PICASO method. The pulse temporal intensity and phase are calculated by use of the PICASO algorithm from the measure spectrum and second-order intensity autocorrelation. Both pulses exhibit the same trend. The difference between the retrieved pulse by PICASO and the pulse obtained through simulation differs by approximately 150 fs. This difference may be due to additional dispersion encountered in the experimental setup prior to the intensity correlation measurements, minor inaccuracies in the PICASO algorithm, or the finite resolution of the temporal grid used in the simulation.

FIG. 38 shows simulation of lock-up of the dispersion-managed breathing-mode semiconductor mode-locked ring laser to externally injected Gaussian pulses. Lock-up is achieved after less than approximately 50 cavity round trips.

FIG. 39 shows a comparison of the measured and the Fourier limited calculated second-harmonic autocorrelation of externally compressed pulses from the experimental set-up of FIG. 29a. The set-up 2904 for measurements of spectra as well as autocorrelation and cross-correlation traces is used without the delay line 2950 in the diagnostics part. Linearly-chirped pulses from the laser output 2915 after the cavity gain media 2910 are compressed using a dual-grating external cavity compressor 2947. The bandwidth-limited autocorrelation is calculated from the measured spectrum of the laser output after the gain element as in (a) of FIG. 30. The calculated autocorrelation FWHM of approximately 404 fs is only approximately 10% shorter than the measured FWHM of approximately 445 fs. From this, we can conclude that efficient intracavity linear chirping and amplification as well as external cavity amplification and compression are achieved.

FIG. 40 shows the pulse temporal intensity and phase retrieved by the PICASO algorithm. The pulses from the output after the gain medium are externally compressed to FWHM of approximately 274 fs. A measured average amplified power of approximately 6.25 mW after external compression at the repetition rate of approximately 323 MHz would correspond to pulse energy of approximately 19 pJ with peak power approximately 70 W and a focused intensity of approximately 1 GW/cm².

SHG-FROG Experimental Results

FIG. 41a shows an experimental setup of dispersion-managed breathing-mode semiconductor mode-locked α-ring
The invention has applications in surgery such as ophthalmic surgery, photo-refractive surgery, glaucoma treatment, and corneal refractive surgery to correct refractive problems such as nearsightedness and astigmatism. Surgical procedures such as laser channel cuts for intra-corneal ring segment (ICRS) implantation, femtosecond lamellar keratoplasty (FLK), and intrastromal vision correction, that rely on ultra-short pulsed lasers, are in development. Additionally, the invention can be used for photodynamic therapy of various carcinomas, for hard tissue ablation in dental procedures, and for multiple surgical procedures that have heretofore been performed with a surgical scalpel or a longer-pulsed laser.

The invention can be used for high-speed diagnostic applications such as multi-photon imaging, optical coherence tomography (OCT), and terahertz imaging. The invention can be used to measure optical-matter phenomena in condensed matter materials, to measure very fast events, processes, mechanisms, interactions, and the like.

Such applications are useful not only for medical diagnosis, but also in the study of chemical reactions at the atomic and molecular level.

The invention has applications in the material sciences. Ultra-short pulsed lasers can be used for material processing by way of non-thermal ablation and deposition of materials.

The invention has applications for commercial information networks, along with military and aerospace optical signal processing systems. In communications, the invention can be used as a high-speed transmitter of optical data in fiber optic networks.

In computers, the invention can be used as a transmitter of optical data, as high speed processors of optical data, and as high speed switches of optical data, and the like.

Additionally the invention can be used in the communication through free space.

While the invention has been described, disclosed, illustrated and shown in various terms of certain embodiments or modifications which it has presumed in practice, the scope of the invention is not intended to be, nor should it be deemed to be, limited thereby and such other modifications or embodiments as may be suggested by the teachings herein are particularly reserved especially as they fall within the breadth and scope of the claims here appended.

We claim:

1. An extreme chirped pulse amplifier (XCPA) laser, comprising:
   a mode-locked semiconductor laser as an oscillator for generating optical pulses;
   a first chirped fiber Bragg grating for stretching temporal duration of the optical pulses so the duration becomes greater than storage time of an amplifying medium of an optical amplifier to generate stretched optical pulses;
   a second chirped fiber Bragg grating for receiving and compressing the stretched optical pulses, wherein optical power of the compressed optical pulse is increased at least approximately 100 times; and
   the optical amplifier operatively arranged to amplify the compressed optical pulses to generate higher power optical pulses.

2. The laser of claim 1, wherein the oscillator includes:
   a gain-flattened mode-locked laser source.

3. The laser of claim 1, wherein the second chirped fiber Bragg grating includes:
   a dual pass grating compressor.

4. The laser of claim 1, further comprising:
   a modulator for modulating the optical pulse wherein the pulse is further shortened.
5. The laser of claim 4, wherein the modulator includes: a passive modulator.

6. A method of generating an extreme chirped pulse amplification (XCPA) effect in an oscillator, comprising the steps of:

- generating optical pulses from a mode locked laser with semiconductor gain medium as an oscillator;
- stretching temporal duration of the optical pulses so the duration becomes greater than storage time of an amplifying medium of a semiconductor optical amplifier;
- compressing the stretched optical pulses to increase the optical power of the compressed optical pulses, wherein optical power of the compressed optical pulses is increased at least approximately 100 times;
- amplifying the compressed optical pulses by the amplifier; and
- outputting optical pulses from the amplified pulses for the extreme chirped pulse amplification.

7. The laser of claim 1, wherein the first grating and the second grating are at different values to one another.

8. The laser of claim 7, wherein the first grating includes a chirped fiber Bragg grating, and the second grating includes a dual pass grating compressor.

9. The method of claim 6, wherein the amount of stretching and the amount of compressing are not equal to one another.

10. The method of claim 9, further comprising the steps of: providing a chirped fiber Bragg grating for the stretching step; and providing a dual pass grating compressor for the compressing step.

11. A method of claim 5, wherein passive modulator is a multiple quantum well saturable absorber.

12. An extreme chirped pulse amplifier (XCPA) laser, consisting of:
- a mode-locked semiconductor laser as an oscillator for generating optical pulses;
- a first optical device for stretching temporal duration of the optical pulses so the duration becomes greater than storage time of semiconductor gain medium of an amplifier to generate stretched optical pulses;
- a second optical device for receiving and compressing the stretched optical pulses, wherein optical power of the compressed optical pulse is increased at least approximately 100 times; and
- the amplifier for amplifying the compressed optical pulses to generate high power optical pulses.
