ABSTRACT
A solid state energy conversion device and method of making is disclosed for converting energy between electromagnetic and electrical energy. The solid state energy conversion device comprises a wide bandgap semiconductor material having a first doped region. A thermal energy beam is directed onto the first doped region of the wide bandgap semiconductor material in the presence of a doping gas for converting a portion of the first doped region into a second doped region in the wide bandgap semiconductor material. In one embodiment, the solid state energy conversion device operates as a light emitting device. In another embodiment, the solid state energy conversion device operates as a photovoltaic device.

BACKGROUND OF THE INVENTION

1. Field of the Invention

This invention relates to solid state devices and more particularly to solid state devices for converting energy between electromagnetic and electrical energy such as light emitting device and photovoltaic device.

2. Background of the Invention

A variety of semiconductors including GaN (Gallium Nitride), GaP (Gallium Phosphide), AlGaAs (Aluminum Gallium Arsenide), InP (Indium Phosphide), Si (Silicon) and SiC are currently being studied for light emitting diode (LED) applications. Recently, efficient luminescence has been discovered in silicon, which is an indirect bandgap semiconductor, due to alteration of its defect states [Wai Lek Ng, et al., Nature, Vol. 410, Issue 8 (2001)]. However in SiC, an indirect bandgap wide-bandgap semiconductor (WBGS) generally emitting in the blue spectra, no efficient radiative isoelectronic trap has been discovered; consequently development of this LED material has languished. Other recent papers show that SiC LEDs have potential for high quantum efficiency (a) S. I. Vlaskina, “Silicon Carbide LED”, Semiconductors, Quantum Electronics & Optoelectronics, 2002, Vol. 5, No. 1, pp 71-75, b) S. Kamiyama et al, “Extremely high quantum efficiency of donor-acceptor-pair emission in N- and B-doped 6H—SiC, JAP, 99, 093108 (2006)].

P-type doping, particularly exhibiting low resistivity, has been a drawback for wide-bandgap semiconductor LED material candidates. Ion implantation and thermal diffusion are currently the most widely used techniques for doping semiconductors. The energy scattered by the decelerating ions leads to crystal damage by introducing point defects and the formation of amorphous material. Post ion implantation high temperature annealing isothermally heats the wafer inducing undesirable dopant diffusion in previously prepared layers.

Doping is one of the challenges for wide bandgap semiconductors, particularly SiC, device fabrication due to its hardness, chemical inertness and the low diffusion coefficient of most impurities I. A. Salama, Ph.D. Dissertation, University of Central Florida, Spring (2003). Current doping methods used for SiC device fabrication include epitaxy layer and ion implantation. Maximum doping concentration is limited by the solubility dopant depth is limited by the mass diffusion coefficient of the dopant in the wide bandgap semiconductor substrate. Epilayer doping is in situ doping during chemical vapor deposition epitaxial growth and is limited in SiC to nitrogen (N) or phosphorous (P) for n-type, aluminum (Al) or boron (B) for p-type and vanadium (V) for semi-insulating type. Ion implantation is the most common doping technique used for wide bandgap semiconductor devices. This process generates implantation-induced defect centers including amorphization in the wafer and requires high annealing temperatures to remove these defects and to electrically activate the dopants. In SiC some defects remain after annealing at temperatures up to 1700° C. [Z. Tian, N. R. Quick, and A. Kar, Acta Materialia, Vol. 53, (2005), pp. 2835-2844]. Annealing at these temperatures can cause severe surface damage due to silicon sublimation and redistribution [Z. Tian, N. R. Quick and A. Kar, Acta Materialia, 54, 4273, (2006)]. In summary conventional doping processes limit the dopant species, dopant concentrations and create defects.

U.S. Patent No. 5,063,421 to Suzuki et al. discloses a silicon carbide light emitting diode having a p-n junction is disclosed which comprises a semiconductor substrate, a first silicon carbide single-crystal layer of one conductivity formed on the substrate, and a second silicon carbide single-crystal layer of the opposite conductivity formed on the first silicon carbide layer, the first and second silicon carbide layers constituting the p-n junction, wherein at least one of the first and second silicon carbide layers contains a tetravalent transition element as a luminescent center.

U.S. Patent No. 5,243,204 to Suzuki et al. discloses a silicon carbide light emitting diodes having a p-n junction which is constituted by a p-type silicon carbide single-crystal layer and an n-type silicon carbide single-crystal layer formed thereon. In cases where light emission caused by recombination of free excitons is substantially utilized, at least a part of the n-type silicon carbide layer adjacent to the interface of the p-n junction is doped with a donor impurity at a concentration of 5x1016 cm-3 or lower. In cases where light emission caused by acceptor-associated recombination is substantially utilized, the p-type silicon carbide layer is doped with an acceptor impurity and at least a part of the n-type silicon carbide layer adjacent to the interface of the p-n junction is doped with a donor impurity at a concentration of 1x1018 cm-3 or higher. Also provided are a method for producing such silicon carbide light emitting diodes and a method for producing another silicon carbide light emitting diode.

U.S. Patent No. 5,416,342 to Edmond et al. discloses a light emitting diode is disclosed that emits light in the blue portion of the visible spectrum with high external quantum efficiency. The diode comprises a single crystal silicon carbide substrate having a first conductivity type, a first epitaxial layer of silicon carbide on the substrate and having the same conductivity type as the substrate, and a second epitaxial layer of silicon carbide on the first epitaxial layer and having the opposite conductivity type from the first layer. The first and second epitaxial layers forming p-n junction, and the diode includes Ohmic contacts for applying a potential difference across the p-n junction. The second epitaxial layer has side walls and a top surface that forms the top surface of the diode, and the
second epitaxial layer has a thickness sufficient to increase the solid angle at which light emitted by the junction will radiate externally from the side walls, but less than the thickness at which internal absorption in said second layer would substantially reduce the light emitted from said top surface of the diode.

U.S. Pat. No. 6,900,465 to Nakamura et al. discloses a nitride semiconductor light-emitting device having an active layer of a single-quantum well structure or a multi-quantum well made of a nitride semiconductor containing indium and gallium. A first p-type clad layer made of a p-type nitride semiconductor containing aluminum and gallium is provided in contact with one surface of the active layer. A second p-type clad layer made of a p-type nitride semiconductor containing aluminum and gallium is provided on the first p-type clad layer. The second p-type clad layer has a larger band gap than that of the first p-type clad layer. An n-type semiconductor layer is provided in contact with the other surface of the active layer.

U.S. Pat. No. 6,998,970 to Nakamura et al. discloses a gallium nitride-based III-V Group compound semiconductor device having a gallium nitride-based III-V Group compound semiconductor layer provided over a substrate, and an Ohmic electrode provided in contact with the semiconductor layer. The Ohmic electrode is formed of a metallic material, and has been annealed.

U.S. Pat. No. 7,045,375 to Wu et al. discloses a white-light emitting device comprising a first PRS-LED and a second PRS-LED. The first PRS-LED has a primary light source to emit blue light and a secondary light source to emit red light responsive to the blue light; and the second PRS-LED has a primary light source to emit green light and a secondary light source for emitting red light responsive to the green light. Each of the primary light sources is made from an InGaN layer disposed between a p-type GaN layer and an n-type GaN layer. The secondary light sources are made from AlGaN. The primary light source and the secondary light source can be disposed on opposite sides of a sapphire substrate. Alternatively, the secondary light source is disposed on the n-type GaN layer of the primary light source. The second light sources may comprise micro-rods of AlGaN of same or different compositions.

Discussion of wide bandgap materials and the processing thereof are discussed in U.S. Pat. No. 5,391,841; U.S. Pat. No. 5,793,042; U.S. Pat. No. 5,837,607; U.S. Pat. No. 6,025,609; U.S. Pat. No. 6,054,375; U.S. Pat. No. 6,271,576, U.S. Pat. No. 6,670,693, U.S. Pat. No. 6,930,009 and U.S. Pat. No. 6,939,748 are hereby incorporated by reference into the present application.

Therefore, it is an objective of this invention to provide a solid state energy conversion device and method of making that incorporates a process for doping conventional and unconventional dopants in direct wide bandgap semiconductors to create efficient radiative states to provide an efficient solid state energy conversion device.

Another objective of this invention is to provide a solid state energy conversion device and method of making that incorporates combinations of dopants which enables the tuning of solid state energy conversion device to a white light sensitivity of the solid state energy conversion device.

The foregoing has outlined some of the more pertinent objects of the present invention. These objects should be construed as being merely illustrative of some of the more prominent features and applications of the invention. Many other beneficial results can be obtained by modifying the invention within the scope of the invention. Accordingly other objects in a full understanding of the invention may be had by referring to the summary of the invention, the detailed description describing the preferred embodiment in addition to the scope of the invention defined by the claims taken in conjunction with the accompanying drawings.

SUMMARY OF THE INVENTION

The present invention is defined by the appended claims with specific embodiments being shown in the attached drawings. For the purpose of summarizing the invention, the invention relates to a solid state energy conversion device and a method of making for converting energy between electromagnetic and electrical energy. The solid state energy conversion device comprises a wide bandgap semiconductor material having a first doped region. A doping gas is applied to the first doped region of the wide bandgap semiconductor material. A thermal energy beam is directed onto the first doped region of the wide bandgap semiconductor material in the presence of the doping gas for converting a portion of the first doped region into a second doped region in the wide bandgap semiconductor material. A first and a second Ohmic contact are applied to the first and the second doped regions of the wide bandgap semiconductor material.

In another specific embodiment of the invention, a doping gas to the first doped region of the wide bandgap semiconductor material comprises applying a doping gas selected from the group consisting of silicon carbide, gallium nitride, aluminum nitride, diamond, diamond like carbon, boron nitride and gallium phosphide.

In another specific embodiment of the invention, the step of applying a doping gas to the first doped region of the wide bandgap semiconductor material comprises applying a dopant atom to the first doped region of the wide bandgap semiconductor material comprising applying a doping gas containing a dopant atom having a valence sufficiently greater than the valence of the wide bandgap semiconductor material to provide a multi-hole donor within the first doped region of the wide bandgap semiconductor material. Alternatively, the step of applying a doping gas to the first doped region of the wide bandgap semiconductor material comprises applying a doping gas containing a dopant atom having a valence sufficiently greater than the valence of the wide bandgap semiconductor material to provide a multi-hole acceptor within the first doped region of the wide bandgap semiconductor material. The step of applying the first and second Ohmic contact may comprises applying the first and second Ohmic contact selected from the group consisting of indium, aluminum and laser synthesized carbon rich conductor.
The solid state energy conversion device may operate as a light emitting device or a photovoltaic device. The solid state energy conversion device produces electromagnetic radiation upon the application of electrical power to the first and second Ohmic contacts to operate as a light emitting device. The solid state energy conversion device produces electrical power between the first and second Ohmic contacts upon the application of electromagnetic radiation to operate as a photovoltaic device.

In another embodiment of the invention, the invention is incorporated into solid state energy conversion device comprising a wide bandgap semiconductor material having a first doped region. A second doped region is formed in situ within a portion of the first doped region by directing a thermal energy beam onto the first doped region in the presence of a doping gas for converting a portion of the first doped region into a second doped region. A first and a second Ohmic contact is connected to the first and the second doped regions of the wide bandgap semiconductor material. In one example, the solid state energy conversion device operates as a light emitting device to produce electromagnetic radiation upon the application of electrical power to the first and second Ohmic contacts. In another example, the solid state energy conversion device operates as a photovoltaic device to produce electrical power between the first and second Ohmic contacts upon the application of electromagnetic radiation.

In still another embodiment of the invention, the invention is incorporated into the process of making a solid state light emitting device in a substrate of a wide bandgap semiconductor material. The process comprises the steps of providing a wide bandgap semiconductor material having a first doped region. A doping gas is applied to the first doped region of the wide bandgap semiconductor material. A thermal energy beam is directed onto the first doped region of the wide bandgap semiconductor material in the presence of the doping gas for converting a portion of the first doped region into a second doped region in the wide bandgap semiconductor material. A first and a second Ohmic contact is applied to the first and the second doped regions of the wide bandgap semiconductor material. In one example, the solid state energy conversion device produces electromagnetic radiation upon the application of electrical power to the first and second Ohmic contacts to operate as a light emitting device having a color temperature that is between bright midday daylight and average daylight. In another example, the solid state energy conversion device produces electromagnetic radiation upon the application of electrical power to the first and second Ohmic contacts to operate as a light emitting device having a color temperature that is between bright midday daylight and average daylight.

In still another embodiment of the invention, the invention is incorporated into a solid state light emitting device comprising a wide bandgap semiconductor material having a first doped region. A second doped region is formed in situ within a portion of the first doped region by directing a thermal energy beam onto the first doped region in the presence of a doping gas for converting a portion of the first doped region into a second doped region. A first and a second Ohmic contact are connected to the first and the second doped regions of the wide bandgap semiconductor material.

In a further embodiment of the invention, the invention is incorporated into a solid state photovoltaic device comprising a wide bandgap semiconductor material having a first doped region. A second doped region is formed in situ within a portion of the first doped region by directing a thermal energy beam onto the first doped region in the presence of a doping gas for converting a portion of the first doped region into a second doped region. A first and a second Ohmic contact are connected to the first and the second doped regions of the wide bandgap semiconductor material.

BRIEF DESCRIPTION OF THE DRAWINGS

For a fuller understanding of the nature and objects of the invention, reference should be made to the following detailed description taken in connection with the accompanying drawings in which:

FIG. 1 is a side view of an air-tight chamber with a thermal energy beam impinging on a wide-bandgap semiconductor substrate for forming a solid state energy conversion device of the present invention;

DETAILED DISCUSSION

FIG. 1 is a side view of an apparatus 5 for forming a solid state energy conversion device 10 on a wide-bandgap semiconductor substrate 20. The wide-bandgap semiconductor substrate 20 is shown located in a air-tight chamber 30. The chamber 30 has an inlet valve combination 31 and outlet valve 32 connected to the side wall of the chamber 30 for injecting and removing gases into and out of the chamber 30, respectively. The chamber 30 includes an airtight transmission window 34. The chamber 30 is disposed on a support member 36 forming an airtight seal therewith.

FIG. 2 is an enlarged isometric view of the solid state energy conversion device 10 formed in situ within the wide-bandgap semiconductor substrate 20 shown in FIG. 1. The wide-bandgap semiconductor substrate 20 defines a first and a second side 21 and 22 and a peripheral edge 23. Although the wide-bandgap semiconductor substrate 20 is shown as a square, the present invention is not limited by the physical configuration of the wide-bandgap semiconductor substrate 20 as shown herein.

Preferably, the wide-bandgap semiconductor 20 has a bandgap greater than 2.0 electron volts. In one example, the wide-bandgap semiconductor 20 is selected from the group IV of the periodic table and having a bandgap greater than 2.0 electron volts. In a more specific example of the invention, the wide-bandgap semiconductor 20 is essentially a single crystal structure.

A thermal energy beam 40 is shown emanating from a source 42 and passing through the airtight transmission window 34 to impinge on the first surface 21 of the wide-bandgap semiconductor substrate 20. In one example, the thermal energy beam 40 is a beam of charged particles such as a beam of electrons or a beam of ions. In another example, the thermal energy beam 40 is a beam of electromagnetic radiation such as a laser beam. Examples of a suitable source of the laser beam include a Nd:YAG laser, a frequency double 20 NNd:YAG laser or an Excimer laser.

The thermal energy beam 40 is scanned in two dimensions across the first surface 21 of the wide-bandgap semiconductor substrate 20 to form the solid state energy conversion device 10. In this example, the first surface 11 of the solid state energy conversion device 10 is coincident with the first surface 21 of the wide-bandgap semiconductor substrate 20 with the remainder of the solid state energy conversion device 10 including the second surface 12 and the peripheral surface 13 being embedded within the wideband gap semiconductor substrate 20.

The thermal energy beam 40 impinges on the wide-bandgap semiconductor substrate 20 to create the solid state energy conversion device 10 within the wide-bandgap semiconductor substrate 20. In this example, the solid state energy conversion device 10 is located on the first side 21 of the wide-bandgap semiconductor substrate 20. The solid state energy conversion device 10 is shown as a portion of the wide-bandgap semiconductor substrate 20 formed by causing relative movement between the wide-bandgap semiconductor substrate 20 and the thermal energy beam 40.

The wide-bandgap semiconductor substrate 20 may be formed as a monolith or a thin film substrate having suitable properties for forming the solid state energy conversion device 10 in the wide-bandgap semiconductor substrate 20. Laser doping can be conducted on opposing surfaces of a substrate, wafer, thin film, thin film deposited on a flexible substrate or in different regions on the same surface.

Table 1 sets the initial properties of a wide-bandgap semiconductor substrate 20 suitable for creating the solid state energy conversion device 10 of the present invention.
Wide bandgap semiconductors (WBGSs) have been laser doped with both n- and p-type dopants. Specific dopant types and substrates include nitrogen and cobalt in diamond-like carbon; magnesium in GaN; and aluminum, nitrogen, chromium, boron, gallium, europium, erbium, selenium, oxygen and thulium in silicon carbide from metal-organic and powder precursors. Laser doping achieves higher dopant concentration than by conventional ion implantation doping. Nitrogen dopant concentration is increased one to three orders of magnitude while aluminum doping is increased from one to four orders of magnitude compared to ion implantation without creating holes per atom creating more efficient radiative states in indirect wide bandgap semiconductors.

For n-type doping, the sample was placed in nitrogen atmosphere at pressure of 30 psi and laser-doped regions were formed on the sample surface by moving the chamber with a stepper motor-controlled translation stage. The height of the chamber was controlled manually through an intermediate stage to obtain different laser spot sizes on the SiC substrate. In case of gallium phosphide (GaP), nitrogen acts as an iso-electronic defect rather than a n-type dopant. For p-type doping, TMA (trimethylaluminum, (CH₃)₃Al), Bis(ethyl benzene)-chromium and boron were used. TMA was heated in the bubbler source immersed in a water bath maintained at 100°C until it evaporated and then a carrier gas, methane, was passed through the bubbler to transport the TMA vapor to the laser doping chamber. Similarly for chromium doping, Bis(ethyl benzene)-chromium was heated in a bubbler source immersed in a water bath maintained at 100°C until it evaporated and then a carrier gas, argon, was passed through the bubbler to transport the ethyl benzene chromium vapor to the laser doping chamber. These dopant gas species decompose at the laser-heated substrate surface producing Al and Cr atoms, which subsequently diffuse into the substrate. A more detailed discussion follows on the importance of doping with atoms that have a sufficient valence to create multi-hole acceptors. Chromium (6+), which has a valence of two greater than the silicon (4+) component of silicon carbide, is used as a dopant example to create efficient radiative states. Normally dopant atoms are from the adjacent groups in the periodic table that are on either side of the atom of an atomic constituent of the parent wide bandgap semiconductor. For example Si is in group N and elements such as Al (p-type dopant) and P (n-type dopant) are in groups III and V respectively. The transition metal Cr has been doped into SiC, which does not follow this conventional approach. Additionally Cr acts as an acceptor creating two holes per Cr atom (a multi-hole acceptor); higher Cr concentrations greatly increase the acceptor population as confirmed by deep level transient spectroscopy (DLTS). DLTS spectra of a 4H-SiC (n-type-N) wafer substrate laser doped with chromium shows minority carrier trap peaks due to acceptor (holes) states in a chromium-doped 4H—SiC (n-type) wafer, which confirms that chromium is a p-type dopant. The DLTS technique is a pow-

erful tool for determining the defect properties such as defect energy level, capture cross-section, and trap density. A modified DLTS that combines junction spectroscopy with illumination in a double pulse approach can be used to identify the minority carrier traps acting as recombination centers.

The technique is based on the transient capacitance change associated with the thermal emission of charge carriers from a trap level to thermal equilibrium after an initial non-equilibrium condition in the space-charge region of a Schottky barrier or a p-n junction diode. The polarity of the DLTS peak depends on the capacitance change after trapping the minority or majority carriers. In general, a minority carrier trap produces a positive DLTS peak, while a majority carrier trap yields a negative DLTS peak. [D. V. Lang, Fast capacitance transient apparatus: Application to ZnO and O centers in GaP p-n junctions, J. Appl. Phys. 45 (1974) 3014-3022.]

The active state of Cr was confirmed by Hall effect measurements using a Cr-doped n-type (nitrogen-doped) 4H—SiC sample. This sample was prepared using the same laser doping parameters as used for laser doping Cr into the p-type 4H—SiC wafer. The Hall measurement identified the Cr-doped region as p-type with a carrier concentration of 1.9x10^19 cm^-3 which is almost twice the average dopant concentration (~1x10^19 cm^-3). The average dopant concentration is based on the Secondary Ion Mass Spectroscopy (SIMS) data for n-type 4H—SiC with a concentration of 2x10^16 cm^-3 at the wafer surface and 10^17 cm^-3 at a depth of 500 nm. This data confirms Cr as a double acceptor and also indicate that the laser doping technique activated all the dopant atoms without the need of any additional annealing step.

Conversely, SiC can be doped with fewer Cr atoms than Al atoms to achieve the same hole concentration. Fewer Cr atoms in the SiC lattice is expected to produce less strain and defects in the material than in the case of higher concentrations of Al.

Similarly, multi-electron donors can be laser doped into SiC. Europium having a +2 valence, derived from a Europium Tetramethyl, 3.5 heptaneonate precursor vapor decomposes upon laser heating and is diffused into SiC substrate using the process described for Cr laser doping. Selenium derived from a diethylselenium precursor also behaves as a multi-electron donor.

Laser doping can convert indirect bandgap semiconductors to direct bandgap semiconductors by intentionally inducing strain to alter electron momentum states. An indirect bandgap semiconductor has a conduction band bottom that does not occur at momentum (k)=0 while the top of the valence band does occur at k=0. Therefore energy released during electron recombination with a hole is converted primarily into a phonon (additional momentum), a quasi-particle which is a quantized sound wave; e.g. Si, GaP, SiC. A direct bandgap semiconductor has a conduction band bottom and valence band top occurring at the momentum k=0. Therefore energy released during band-to-band electron recombination with a hole is converted primarily into photon radiation (radiant recombination) exhibiting a wavelength determined by the energy gap; e.g. GaAs, InP, GaN; no extra momentum is required. Direct bandgap semiconductors are sometimes referred to as "optically active" and indirect as "optically inactive". Laser doping where the dopant has a valence greater than the highest valence atom of the comprising the parent wide bandgap semiconductor can transform the SiC indirect wide bandgap semiconductor into a direct bandgap semiconductor; dopants with a valence 2 or greater than the highest valence atom comprising the parent wide bandgap semiconductor are preferred. This doping induces strain which alters the momentum state of the electrons and facilitates the transfer of electron-hole recombination between the conduction and valence bands with no additional momentum.

Conversely a solid state photovoltaic device with p and n regions can produce electric current when light or electromagnetic radiation is irradiated on the solid state photovoltaic device.

The laser doping technology of the present invention can be used to create energy conversion devices in many semiconductor structures such as diodes, transistors and other electron components in monolithic or thin film geometries.

FIG. 3A is a side sectional view of a first example of a solid state energy conversion device 10A formed in accordance with the present invention to provide a solid state light emitting device. In this example, the substrate 20A has a first and a second side 21A and 22A and a peripheral edge 23A. A laser doped region 51A is formed on the first side 21A of the substrate 20A. A first and a second Ohmic contact 61A and 62A are electrically connected to the first and second side 21A and 22A of the substrate 20A. The solid state light emitting device 10A produces electromagnetic radiation when an electric current is injected between the first and second Ohmic contacts 61N and 62N as indicated by the battery 71A.

Preferably, the first and second electrodes 61A and 62A are formed by the thermal conversion of the wide-bandgap semiconductor substrate 20A. The conversion of the portions of the wide-bandgap semiconductor substrate 20A to provide the first and second electrodes 61A and 62A is set forth in my U.S. Pat. No. 5,145,741; U.S. Pat. No. 5,391,841; U.S. Pat. No. 5,793,042; U.S. Pat. No. 5,837,607; U.S. Pat. No. 6,025,609; U.S. Pat. No. 6,054,375; U.S. Pat. No. 6,271,576 and U.S. Pat. No. 6,670,693.

FIG. 3B is a side sectional view of a second example of a solid state energy conversion device formed in accordance with the present invention to provide a solid state light emitting device 10B. In this example, the substrate 20B has a first and a second side 21B and 22B and a peripheral edge 23B. Laser doped regions 51B and 52B are formed on the first side 21B of the substrate 20A. A first and a second Ohmic contact 61B and 62B are electrically connected to the laser doped regions 51B and 52B. The solid state light emitting device 10B produces electromagnetic radiation when an electric current is injected between the first and second Ohmic contacts 61B and 62B as indicated by the battery 71B.

FIG. 3C is a side sectional view of a third example of a solid state energy conversion device formed in accordance with the present invention to provide a solid state light emitting device 10C. In this example, the substrate 20C has a first and a second side 21C and 22C and a peripheral edge 23C. Laser doped regions 51C and 52C are formed in layers on the first side 21C of the substrate 20A. A first and a second Ohmic contact 61A and 62A are electrically connected to the first and second side 21C and 22C of the substrate 20C. The solid state light emitting device 10C produces electromagnetic radiation when an electric current is injected between the first and second Ohmic contacts 61C and 62C as indicated by the battery 71C.

FIG. 4A is a side sectional view of a fourth example of a solid state energy conversion device formed in accordance with the present invention to provide a solid state photovoltaic device 10D. In this example, the substrate 20D has a first and a second side 21D and 22D and a peripheral edge 23D. A laser doped region 51D is formed on the first side 21D of the substrate 20D. A first and a second Ohmic contact 61D and 62D are electrically connected to the first and second side 21D and 22D of the substrate 20D. The solid state photovol-
technique device 10D produces an electric current between the first and second Ohmic contacts 61D and 62D upon receiving electromagnetic radiation as indicated by the ammeter 72D.

FIG. 4B is a side sectional view of a fifth example of a solid state energy conversion device formed in accordance with the present invention to provide a solid state photovoltaic device 10E. In this example, the substrate 20E has a first and a second side 21E and 22E and a peripheral edge 23E. Laser doped regions 51E and 52E are formed in the first and second sides 21E and 22E of the substrate 20E. A first and a second Ohmic contact 61E and 62E are electrically connected to the first and second side 21E and 22E of the substrate 20E. The solid state photovoltaic device 10E produces an electric current between the first and second Ohmic contacts 61E and 62E upon receiving electromagnetic radiation as indicated by the ammeter 72E.

FIG. 4C is a side sectional view of a sixth example of a solid state energy conversion device formed in accordance with the present invention to provide a solid state photovoltaic device 10F. In this example, the substrate 20F has a first and a second side 21F and 22F and a peripheral edge 23F. Laser doped regions 51F and 52F are formed in layers on the first side 21F of the substrate 20F. A first and a second Ohmic contact 61F and 62F are electrically connected to the first and second side 21F and 22F of the substrate 20F. The solid state photovoltaic device 10F produces an electric current between the first and second Ohmic contacts 61F and 62F upon receiving electromagnetic radiation as indicated by the ammeter 72F.

FIG. 5 is a graph of diffusivity of various conventional dopants into SiC using conventional doping processes (e.g., thermal, ion implantation). Conventional doping processes also limit the choice of dopants. For example, nitrogen diffusivity in silicon carbide SiC is 5x10^-15 cm^2/sec at a temperature greater than 2500°C and aluminum diffusivity in silicon carbide SiC is 3x10^-14 to 6x10^-15 cm^2/sec at a temperature greater than 1200°C using conventional doping techniques. The process of laser doping of the present invention increases nitrogen diffusivity in silicon carbide SiC between 2x10^-8 and 9x10^-9 cm^2/sec and increases aluminum diffusivity in silicon carbide SiC between 1x10^-5 and 1x10^-6 cm^2/sec. The process of laser doping of the present invention enables the use of new species of dopants including chromium (Cr), europium (Eu) and selenium (Se) with wide bandgap substrates.

Laser doping, a non-equilibrium process, enables achievement of very high dopant concentrations at the surface, which can exceed the solubility limit. Z. Tian, N. R. Quick and A. Kar, Acta Materialia, 54, 4273. (2006) have shown that laser doping enhances the diffusion coefficient of aluminum and nitrogen in SiC by about six orders of magnitude when compared to conventional doping techniques. It readily facilitates the formation of dopant concentration gradients along the depth of the wafer, i.e., the concentration decreases gradually along the depth. A linearly graded junction can be obtained that further facilitates the effective electron-hole recombination within the depletion region for light emitting applications, E. Fred Schubert, “Light Emitting Diodes”, Cambridge University Press, (2003).

A PHI Adept 1010 Dynamic Secondary Ion Mass Spectroscopy system (SIMS) was used to determine the dopant concentration and its variation along the depth for the p and n regions of the device. An aluminum-doped SiC standard (1x10^19 cm^-3), Cr-implanted SiC standard (1x10^20 cm^-3), N-doped SiC standard (5x10^19 cm^-3), as received 4H—SiC (p-type) and an as-received 6H—SiC (n-type) (5x10^18 cm^-3) were also analyzed for reference and background concentrations.

FIG. 6A is a graph of concentration of the dopants Cr, N and Al as a function of depth within a 4H—SiC silicon carbide wide bandgap substrate 20. In case of a 4H—SiC silicon carbide wide bandgap substrate 20, a very high concentration of about 2x10^20 cm^-3 was measured for Al at the surface decreasing gradually to 1x10^18 cm^-3 to a depth of 700 nm, while a concentration of 1x10^19 cm^-3 was measured for Cr at the surface decreasing gradually to the background concentration of 1x10^17 cm^-3 at a depth of 420 nm. The penetration depth of Al is much larger than that of Cr due to the size effect of these elements. Aluminum is much smaller than Cr and slightly smaller than Si and it can penetrate SiC easily and occupy the available Si vacancies. For Cr occupancy of Si vacancies the penetration is accompanied by lattice strain. Additionally, the solid solubility limits in SiC for Al (2x10^21 cm^-3) is much higher than Cr (3x10^17 cm^-3). G. L. Harris, “Properties of silicon carbide”, IEE Inspec publication, emis data review series 13, (1995).

The concentration of Cr at the surface is about two orders of magnitude higher than the solid solubility limit, while for aluminum it is very close to the solubility limit.

FIG. 6B is a graph of concentration of the dopants Cr, N and Al as a function of depth within a 4H—SiC silicon carbide wide bandgap substrate 20. In case of a 4H—SiC silicon carbide wide bandgap substrate 20, a very high concentration of approximately 1x10^21 cm^-3 was obtained for N at the surface decreasing gradually to 3x10^17 cm^-3 to a depth of 8.5 μm, while a concentration of 1.5x10^19 cm^-3 is obtained for Cr at the surface decreasing gradually to the background concentration of 1x10^18 cm^-3 at a depth of 80 nm. The penetration depth of N is much larger than that of Cr, which results from the atomic radius difference. The smaller nitrogen atom can penetrate SiC easily and occupy the available C or Si vacancies. Also, the solid solubility limits in SiC for N (6x10^20 cm^-3) is much higher than Cr (3x10^17 cm^-3). These dopant concentration levels and their penetration depths can be altered easily by modifying the doping parameters. Laser doping thus provides this advantage and is compatible with both conventional (e.g., Al, N) and unconventional (e.g., Cr) dopants.

FIG. 7 is a graph of operating temperature as a function of bandgap for various types of p-n junctions semiconductors. Since crystalline SiC is chemically inert and has good thermo-mechanical properties at high temperatures, photovoltaic device made of p-n regions in SiC can be located at the walls of combustion chambers, particularly in power plants, to directly convert radiative energy, e.g., heat, into electrical energy. Burning fuels and the resultant flames produce electromagnetic radiation in the ultraviolet (UV), visible and infrared regions of the spectrum. The combustion chamber is modified to contain stacks of SiC photovoltaic cells so that each stack can absorb the radiation of a selected wavelength range to directly produce electricity.

Light Emitting Device

FIG. 8A is a side sectional view of a first example of a light emitting device 10G fabricated on 6H:SiC (n-type) substrate 20G by doping with aluminum and chromium. The substrate 20G defines a first and a second side 21G and 22G and a peripheral edge 23G. A first and a second Ohmic contact 61G and 62G are electrically connected to the first and second side 21G and 22G of the substrate 20G.

Table 2 sets forth the parameters for the fabrication of the light emitting device 10G of FIG. 8A. It should be appreciated by those skilled in the art that Table 2 is a specific example and that numerous other parameters may be used to fabricate light emitting devices having different characteristics.
FIG. 8B is a graph of light intensity as a function of wavelength for the light emitting device 10G of FIG. 8A. The graph of FIG. 8B illustrates the distribution of light intensity, in arbitrary units, as a function of frequency for the light emitting device 10G of FIG. 8A. The sum of the distribution of light intensity of the light emitting device 10G results in a white light. The white light emission is created by laser doping with aluminum and chromium. A broad EL spectrum starting from 400 nm (band gap of 6H—SiC) to 900 nm covering the entire visible spectrum is observed. The red luminescence results form a nitrogen excitation and other defect states luminescence. The green and blue luminescence result from donor-acceptor pair recombination between N—Cr and N—Al, respectively. This red-green-blue (RGB) combination produces an observed broadband white light.

Current LED technology has shortcomings with matching color rendering index and color temperature of sunlight. The color rendering index (CRI), is a measure of the ability of a light source to reproduce the colors of various objects being lit by the source. It is a method devised by the International Commission on Illumination (CIE). The human eye has receptors for short (S), middle (M), and long (L) wavelengths, also known as blue, green, and red receptors. That means that one, in principle, needs three parameters to describe a color sensation. A specific method for associating three numbers (or tristimulus values) with each color is called a color space, of which the CIE XYZ color space is one of many such spaces. However, the CIE XYZ color space is special, because it is based on direct measurements of the human eye, and serves as the basis from which many other color spaces are defined.

In the CIE XYZ color space, the tristimulus values are not the S, M, and L stimuli of the human eye, but rather a set of tristimulus values called X, Y, and Z, which are also roughly red, green and blue, respectively. Two light sources may be made up of different mixtures of various colors, and yet have the same color (metamerism). If two light sources have the same apparent color, then they will have the same tristimulus values, no matter what different mixtures of light were used to produce them.

"Visible light" is commonly described by its color temperature. A traditional incandescent light source's color temperature is determined by comparing its hue with a theoretical, heated black-body radiator. An incandescent light is very close to being a black-body radiator. However, many other light sources, such as fluorescent lamps, do not emit radiation in the form of a black-body curve, and are assigned what is known as a correlated color temperature (CCT), which is the color temperature of a black body which most closely matches the lamp's perceived color. Because such an approximation is not required for incandescent light, the CCT for an incandescent light is simply its unadjusted kelvin value, derived from the comparison to a heated black-body radiator. Bright midday sun is 5200 K and average daylight, and electronic flash, is 5500 K.

The color rendering index of the white light emitting diode as per the 1931 CIE chromaticity at 2 degree on 6H—SiC (n-type) silicon wafer substrate laser doped with aluminum and chromium has the following tristimulus values; X=0.3362, Y=0.3424 and Z=0.3214 which confirms white color space. These values render a color temperature of 5338 K which is very close to the incandescent lamp (or black body) and lies between bright midday sun (5200 K) and average daylight (5500 K).

FIG. 9A is a side sectional view of a first example of a light emitting device 10H fabricated on 4H:SiC (p-type) substrate 20H by doping with a nitrogen and chromium. The substrate 20H defines a first and a second side 21H and 22H and a peripheral edge 23H. A first and a second Ohmic contact 61H and 62H are electrically connected to the first and second side 21H and 22H of the substrate 20H.

Table 3 sets forth the parameters for the fabrication of the light emitting device 10H of FIG. 9A. It should be appreciated by those skilled in the art that Table 3 is a specific example and that numerous other parameters may be used to fabricate light emitting devices having different characteristics.

FIG. 9B is a graph of light intensity as a function of wavelength for the light emitting device 10H of FIG. 9A. The graph of FIG. 9B illustrates the distribution of light intensity as a function of frequency for the light emitting device 10H of FIG. 9A. The sum of the distribution of light intensity of the light emitting device 10H results in a white light. White light emission is created by laser doping with both nitrogen and chromium. A broad spectrum extending from 380 nm (band gap of 4H—SiC) to 850 nm is observed. Green and blue wavelengths are observed due to the occurrence of radiative recombination transitions between donor-acceptors pairs of...
N—Cr and N—Al respectively, while prominent violet wavelength was observed due to nitrogen-valence band level transitions. The red luminescence was mainly due to nitrogen exciton and other defect levels. This red-green-blue (RGB) combination produces an observed broadband white light. The color rendering index for this white light emitting diode as per the 1931 CIE chromaticity at 2 degree has the following tristimulus values; $X = 0.3322$, $Y = 0.3320$ and $Z = 0.3358$. The color temperature is 5510 K which is very close to average daylight (5500 K).

FIG. 10A is a side sectional view of a first example of a light emitting device 101 fabricated on 4H-SiC (p-type) substrate 201 by doping with chromium. Table 4 sets forth the parameters for the fabrication of the light emitting device 101 of FIG. 7A. The sum of the distribution of light intensity of the light emitting device 10M results in a blue-green light.

Photovoltaic Device

An optical device with p and n regions can produce electric current when light or electromagnetic radiation is irradiated on the device. These devices are called photovoltaic cells. The photovoltaic device is fabricated using the same processing and p-n junction structure as our white SiC light emitting diode (LED). The laser doping technology can be used to create any semiconductor structure including transistor structures to create photovoltaic devices.

The p and n regions of the photovoltaic device were fabricated by laser doping a p-type 6H—SiC (as-received nitrogen concentration of 5x1018 cm^-3) and p-type 4H—SiC (Al doped) (as received aluminum concentration 1x1019 cm^-3) wafer substrates with respective dopants. Cr and Al were used as p-type dopants while N was used as n-type dopant. A Q-switched Nd:YAG pulse laser (1064 nm wavelength) was used to carry out the doping experiments. The experimental parameters for laser doping of Cr and N were: power 11-13 W, frequency 5-10 kHz for a spot size of 85-150 µm at a scan speed of 0.5-0.8 mm/s.

For n-type doping the sample was placed in a nitrogen atmosphere at pressure of 30 psi and laser-doped regions were formed on the sample surface by moving the chamber with a stepper motor-controlled translation stage. The height of the chamber was controlled manually through an intermediate stage to obtain different laser spot sizes on the SiC substrate. For p-type doping, TMA (trimethylaluminum, (C13H3Al) and B(ethyl benzene)-chromium were used. TMA was heated in a bubbler source immersed in a water bath maintained at 70° C. until it evaporated and then a carrier gas, argon, was passed through the bubbler to transport the TMA vapor to the laser doping chamber. Similarly, for chromium doping Bis(ethyl benzene)-chromium was heated in a bubbler source immersed in a water bath maintained at 100° C. until it evaporated and then a carrier gas, argon, was passed through the bubbler to transport the ethyl benzene chromium vapor to the laser doping chamber. These dopant gas species decompose at the laser-heated substrate surface producing Al and Cr atoms, which subsequently diffuse into the substrate.

Since crystalline SiC is chemically inert and has good thermo-mechanical properties at high temperatures, photovoltaic cells made of p-n regions in SiC can be located at the walls of combustion chambers to directly convert radiative energy into electrical energy, particularly in power plants.

Burning fuels and the resultant flames produce electromagnetic radiation in the ultraviolet (UV), visible and infrared regions of the spectrum. The combustion chamber is modified to contain stacks of SiC photovoltaic cells so that each stack can absorb the radiation of a selected wavelength range to directly produce electricity.

Aluminum and Nickel were deposited on p and n regions respectively on the samples prior to photocurrent measurements to serve as contacts. Contacts can also be laser synthesized producing stable carbon rich conductors that can tolerate high temperatures beyond the capability of conventional materials such as Al and Ni.

FIG. 16 is a side sectional view of a solid state photovoltaic device 10N fabricated on 6H-SiC (n-type) substrate by doping with aluminum and chromium. The substrate 20N defines a first and a second side 21N and 22N and a peripheral edge 23N. A first and a second Ohmic contact 61N and 62N are electrically connected to the first and second side 21N and 22N of the substrate 20N. The solid state photovoltaic device 10N produces an electric current between the first and second Ohmic contacts 61N and 62N upon receiving electromagnetic radiation as indicated by the ammeter 72 N.

Photocurrent measurements were conducted using a Keithley pico-ammeter/voltage source Model 6487 was used for carrying out the current measurements, while an Agilent digital multi-meter Model 34401A was used for measuring the voltages and the resistances. The light source was a 50 W tungsten filament lamp.

Without visible light sources a background voltage and current existed in the SiC samples at room temperature (23° C.). Irradiation from a 50 W tungsten filament light source produced a greater than 220% voltage boost and a greater than 4550% current output boost in the laser doped 4H—SiC device. A greater than 540% voltage boost and a greater than 1250% current output boost was observed in the laser doped 6H—SiC device.

The mechanism for the observed photocurrent SiC is as follows. When a broadband source of light impinges on the doped SiC structure, the photons with different energies are absorbed, which creates electron hole pairs in the valence band. The photons with energies higher than the band gap of the substrate causes the electron to excite from the valence band (or from impurity levels created by dopants Cr, Al, N) to the conduction band (or some impurity levels). The electron flows through the contact wires generate current and the corresponding voltage.

The photovoltaic device can be laser doped with select dopants or combination of dopants to absorb energy from the complete electromagnetic spectrum. The photovoltaic device can be laser doped with select dopants or combination of dopants to select or filter the range of electromagnetic spectrum energy absorbed using the same laser doping methods described for the LED wavelength emission selectivity.

FIGS. 17 and 18 illustrate a solid state device incorporated into a Gas Splitting Catalysis. The laser doped optical device can be used to create a light emitting device (LED) that activates catalysts that dissociate or split gases such as carbon dioxide. The laser doped optical device can also directly dissociate or directly or assist the splitting of gases by photocatalysis. Devices fabricated in wide bandgap semiconductors such as silicon carbide, gallium nitride, aluminum nitride, diamond and boron nitride can be inserted in high temperature environments allowing the high temperature to also contribute to gas dissociation or splitting. A principal application is the dissociation or splitting of carbon dioxide to alleviate global warming. The objective is the conversion of power generation, turbine and auto CO₂ emissions to CO and
O₂ and further to C and O₂ for fuel and structural uses. Laser doping technology allows the combined use of photolysis, chemical catalysis, thermal catalysis and electrical catalysis to drive gas dissociation/splitting.

EXAMPLE 1

In an example a semiconductor region is first laser doped to create an LED tuned to emit in the electromagnetic spectrum range that dissociates CO₂ and activates chemical catalysts. The top of the semiconductor is laser doped with a chemical catalyst that dissociates CO₂. The semiconductor is preferably a wide bandgap semiconductor (WBGS) such as SiC. The semiconductor can be a porous membrane structure, thin film, fiber or fibrous media. The LED wavelength emission tuning dopants can include Al, Cr, Eu, Se, N and P. The chemical catalyst dopants can include Cr, Ti, Ni, Pd, Fe, and their oxides. The chemical dopants can also include precious metals including Pd and Pt. All dopant precursors for laser doping are preferably gases or metal-organic.

EXAMPLE 2

In a further example silicon can be used as the substrate. The Silicon’s top region can be laser doped with the chemical catalysts. The Silicon’s bottom region can be converted to SiC by laser doping carbon into silicon. The SiC region is then laser doped to create the wavelength emitting tuned LED.

EXAMPLE 3

Referring to Example 2 silicon may be converted to SiC during the dissociation of CO₂. Silicon acts a getter to capture carbon.

EXAMPLE 4

In another example the laser doped WBGS (SiC) is used as an energy conversion device (ECD) to convert heat to electricity. The doping steps are the same as example 1. In this concept CO₂ splitting is electrical plus chemical. The device can be placed in hot exhausts such as produced by turbines or internal combustion engines.

EXAMPLE 5

In a further example the LED region irradiation can be used solely to increase the activity of the catalyst. This allows the use of conventional wavelengths (248-10640 nm) which are readily available as opposed to the specific 147 nm defined in prior art for photolysis of CO₂. (Bruce H. Mahan, Photolysis of Carbon Dioxide, Journal of Chemical Physics, 1960, pgs. 959-965).

EXAMPLE 6

In a further example laser doping can be used to enhance hole (positive charge carrier) concentration in the WBGS to chemically reduce CO₂. In effect the hole acts as a positive charged hydrogen atom (a proton). An energy conversion device created by laser doping will create the electrical bias. FIG. 19 illustrates an optical voltmeter, an optical ammeter and/or an optical power meter. This device is a light-emitting diode (LED) that emits light of a particular wavelength when voltage is applied across the diode. The LED can be fabricated by laser doping silicon carbide (SiC) substrates with p-type and n-type dopants to certain depths of the substrate. The range of the voltage, current and power that can be measured with this device will depend on the dimensions of the parent substrate, its dopant concentrations (intrinsicted, extrinsic or semi-insulating), and the type and amount of laser-doped dopants. Very high voltages (~MV) and currents (hundreds of kAmp) can be measured with this device.

FIG. 20 illustrates a transformer utilizing the present invention. This device is based on the principle of step-down and step-up transformers having armatures with different number of windings of conductive wires. The device can be fabricated using the laser metallization process to create two conductive (laser-metalized) windings of different number of turns inside a SiC substrate.

\[ V_{AB} = \frac{P_R}{\eta} \]

Where

\( P_R \) = Power of the output light from the LED device = Power meter reading

\( \eta \) = Efficiency of the LED device for converting the input power to output power= \( P_R \) / \( P_i \)

\( R \) = Resistance of the LED device

\( V_{AB} \) = Voltage of the power line between points A and B in FIG. 1

\( I_{AB} \) = Current through the power line between points A and B in FIG. 1

\( R_{AB} \) = Resistance of the power line between points A and B in FIG. 1

\( I \) = Current through the LED device

\( P_i \) = Input power to the LED device

Eq. (3) will allow determination of the voltage since all the quantities on the right hand side of Eq. (3) are known.

Knowing \( V_{AB} \) from Eq. (3) and \( R_{AB} \) from the power line material data, the current through the power line between points A and B can be determined as

\[ I_{AB} = \frac{P_R}{R_{AB}} \]

\[ V_{1} = V_{2} = \frac{V_{1}}{N_1} = \frac{V_{2}}{N_2} \]

The present disclosure includes that contained in the appended claims as well as that of the foregoing description. Although this invention has been described in its preferred form with a certain degree of particularity, it is understood that the present disclosure of the preferred form has been made only by way of example and that numerous changes in the details of construction and the combination and arrangement of parts may be resorted to without departing from the spirit and scope of the invention.
What is claimed is:

1. A solid state gas dissociating/splitting device, comprising:
   a substrate having an embedded light emitting device and
   an embedded catalyst device located in proximity to a
   surface of said substrate;
   said embedded light emitting of light for actuating said
   embedded catalyst device to dissociate or to split a gas at
   said surface of said substrate.

2. A solid state gas dissociating/splitting device as set forth
   in claim 1, wherein said embedded light emitting device is
   co-extensive with said embedded catalyst device.

3. A solid state gas dissociating/splitting device as set forth
   in claim 1, including a high positive charge carrier region that
   creates an electrical bias.

4. A solid state gas dissociating/splitting device as set forth
   in claim 1, including a wide bandgap semiconductor region
   and a non wide bandgap semiconductor region.

5. A solid state device for measuring an electrical value of
   an electrical circuit, comprising:
   a substrate comprising a light emitting device connected to
   the electrical circuit for emitting a light of a particular
   wavelength upon the application of an applied voltage;
   and
   a solid state meter for receiving said light of said light
   emitting device to display the electrical value of the
   electrical circuit.

6. A solid state device for measuring an electrical value of
   an electrical circuit, as set forth in claim 5, wherein said solid
   state meter is a solid state ammeter.

7. A solid state device for measuring an electrical value of
   an electrical circuit, as set forth in claim 5, wherein said solid
   state meter is a solid state power meter.

8. A solid state device for measuring an electrical value of
   an electrical circuit, as set forth in claim 5, wherein said solid
   state meter is a solid gate voltmeter.

9. A solid state sensor device, comprising:
   a substrate comprising a first region and a second region;
   said first region of said substrate comprising a solid
   state optical voltmeter; and
   said second region of said substrate comprising a laser
   doped light emitting device.

10. A solid state sensor device as set forth in claim 9,
    wherein said first region of said substrate comprises a solid
    state optical ammeter; and
    said second region of said substrate comprises a laser
    doped light emitting device.

11. A solid state sensor device as set forth in claim 9,
    wherein said first region of said substrate comprises a solid
    state optical power meter; and
    said second region of said substrate comprises a laser
    doped light emitting device.

12. A solid state transformer comprising:
    a wide band gap substrate;
    a first laser metalized conductive windings having a first
    number of windings formed in said wide band gap sub- 
    strate;
    a second laser metalized conductive windings having a
    second number of windings formed in said wide band 
    gap substrate; and
    said first number of windings being different than said
    second number of windings.

13. A solid state transformer as set forth in claim 13,
    wherein said wide band gap substrate is SiC.
