RESEARCH REPORT

Submitted in partial fulfillment of the requirements
for the degree of Master of Science
in the Graduate Studies Program of the College of Engineering
University of Central Florida
Orlando, Florida

Summer Term
1981
ABSTRACT

Orange County, Florida, through its Sewer and Water Department, owns fifty active and ten inactive water treatment plants. These treatment plants have a total of ninety-four supply wells, sixty-four of which are actually in service. Most of these wells were obtained through purchase from private or investor owned utility companies.

A file search was undertaken from records of the Orange County Sewer and Water Department, U.S. Geological Survey, former water system owners, and well drillers in order to compile all available information on these wells. Information was gathered on location, original drilling of the well, static water level and pumping tests, chemical and bacteriological quality of the water, and most recent pump, motor and auxiliary engine. This information was recorded on a data form for each well, with the wells geographically categorized into five areas throughout the County. For each geographical area, mean, high and low values were determined for well and casing depth; static water level; well flow, specific pumping capacity and other flow type parameters; and various water quality parameters, such as total dissolved solids, chloride, sulfide, iron, alkalinity, and hardness
concentrations. These were then compared to each other to see if any patterns could be established for wells in various areas of the County. Comparisons were also made to recorded piezometric surface levels of the Floridan Aquifer and to information in available literature on wells in the Orange County area.

The comparisons indicated wells were slightly shallower in the western part of the County than in the eastern part. Depth to static water level generally increased as you progressed from east to west, with the highest MSL elevations occurring in the southwest. Specific well capacity was greatest in the westerly area. Total dissolved solids content of the wells was much higher than that predicted by the literature, and hardness, iron and sulfide values were higher in the east than in the west.
ACKNOWLEDGEMENTS

I would like to thank my faculty advisor during preparation of this report, Dr. J. Paul Hartman, for his technical guidance and particularly for his patience and the motivation he provided when it appeared my motivation was somewhat lacking.

Many thanks go to Jim Robards, Joe Puryea, and Bob Stewart of the Orange County Sewer and Water Department for their help throughout the gathering of data phase. Also, thanks go to the many well drillers and private utility companies in the Central Florida area for their assistance in obtaining data which was not readily available.

Finally, special appreciation and thanks is extended to my wife, Betty, for tolerating me during the more trying times throughout my Master's Program and particularly for the hours spent in preparation of this report in lieu of being able to spend my time with her.

CHAPTER I

INTRODUCTION

Public water supplies in the Central Florida area are generally from deep wells, rather than from surface water or shallow groundwater aquifers. This is particularly true for Orange County and the various water utility systems within.

Orange County contains many separate public water systems ranging in size from reasonably large (serving a population of approximately 220,000) to very small (serving populations of less than 100). In the past, there was an extensive number of small systems owned by private or investor utility companies. In recent years, the Orange County government has acquired most of these private systems, thereby reducing the total number of public water system owners in the County. At present, in addition to the Orange County government, there are systems owned by the Orlando Utilities Commission (serving the City of Orlando and surrounding areas), General Waterworks Corporation (serving the City of Winter Park and surrounding areas), the cities of Maitland, Apopka, Ocoee and Winter Garden, Reedy Creek Utilities (serving the Walt Disney World area), and a few small private companies. This research report is limited to a study of only the wells owned by the Orange County government.
As most all the wells in the County's systems were acquired from others, and not drilled under their directorship, any information on these wells which the County had in their files had been passed along from the prior owner with the sale of the individual water system. This information was limited, at best, and scattered throughout various files in the offices of the Orange County Sewer and Water Department. The primary purpose of this research report is to compile all information available on each well owned by the County and to record it in a convenient format so that easy access to data from all the wells can be obtained by referring to one source. A secondary purpose is to take the data collected and make comparisons to determine if significant relationships or differences exist between wells drilled throughout the County.

In addition to the employees and the files of the Orange County Sewer and Water Department, information was collected from various well drillers (Central Florida Well Drillers, Inc., 1979; Herron Well Drilling, 1979; Layne Atlantic Company, 1979; Locke Well and Pump Company, 1979; and Meridith Corporation, 1979); various former water system owners (Central Florida Utilities, 1979; General Waterworks Corporation, 1979; Meridith Corporation, 1979; and Southern States Utilities, Inc., 1979); and the United States Geological Survey, Orlando, Florida office. The files of each of these organizations were researched extensively to add to the amount of data already collected for each of the wells owned
by the County. The accuracy of the data shown in succeeding chapters of this report is limited to the accuracy of data in the files researched. The writer disclaims responsibility for any of the data which may be found to be in error through additional research or physical testing. In several instances, conflicting data was collected from different sources for a particular well. In cases where the correct information could not be readily determined, the data from both sources is shown on the data sheet and a reference to the conflict is made.

It is expected that this research report will be most useful to the Orange County Sewer and Water Department. They will have one source to refer to when requiring information on any of their wells, whether it be physical or chemical in nature. It will be helpful to them when problems arise with the wells or well pumps, in that immediate reference will be available to those trouble-shooting the problems. In addition, the County or others interested in drilling a well in the general proximity of wells shown in this report can use these data to project the quantity and quality of water available and the physical characteristics of a well necessary to acquire it.
CHAPTER II
HYDROLOGY IN THE ORANGE COUNTY AREA

Orange County is underlain mostly by marine limestone, dolomite, shale, sand, and anhydrite to about 6500 feet, at which depth granite and crystalline rock of the basement complex occur (Lichtler, et al., 1968). Ground water is obtained from three levels within this range. These are: (1) a non-artesian aquifer composed of clastic material of late Miocene to recent age, (2) several discontinuous shallow artesian aquifers in the Hawthorn Formation of Middle Miocene Age, and (3) the Floridan Aquifer composed of the Ocala Group, the Avon Park Limestone, the Lake City Limestone, the Suwannee Limestone, and the Tampa Limestone, all of Eocene Age, and permeable parts of the Hawthorn Formation that are in hydrologic contact with the rest of the aquifer (Lichtler, et al., 1964).

Non-artesian conditions occur when the upper surface of the zone of saturation (the water table) is not confined and accordingly is free to rise and fall. Artesian conditions occur when an aquifer (water bearing formation) is confined by relatively impermeable beds and the water is under greater than atmospheric pressure.
The heights to which water will rise in tightly cased wells that penetrate an artesian aquifer define its pressure or piezometric surface. The piezometric surface is not directly related to the water table and may be above, below, or at the same level as the water table. Where the water table is above the piezometric surface, the non-artesian water may infiltrate through the confining layer to the artesian aquifer. Such areas are recharge areas to the artesian aquifer. Conversely, where the piezometric surface is above the water table, the artesian water moves upward and the area is a discharge area of the artesian aquifer. As no confining bed is completely impermeable, some leakage up or down usually occurs; however, where the confining bed is composed of a thick section of dense material, such as clay, the amount of leakage is relatively small.

The non-artesian aquifer in Orange County extends from the water table to about 30 or 40 feet below land surface. It is composed mainly of quartz sand with varying amounts of clay, hardpan, and shell material. The non-artesian aquifer extends over most of the County, but its composition and thickness, and consequently its productivity, vary and there may be many local areas where it will not produce enough water to supply a well. Most wells in the non-artesian aquifer are small diameter sand-point or screened wells, 20 to 30 feet deep, that yield small to moderate quantities of water. Practically all the recharge
to this aquifer comes from rainfall within or near the County. Discharge from the aquifer is by evapotranspiration, seepage into surface water bodies, downward leakage to underlying aquifers, seepage out of the County, and pumpage.

Several shallow artesian aquifers occur within the confining beds of the Hawthorn or younger formations at depths ranging from about 60 feet to more than 150 feet below land surface. These aquifers are composed of discontinuous shell beds, thin limestone layers, or permeable sand zones. The shallow artesian aquifers are most productive in the area east and south of Orlando, where they yield quantities of water sufficient for domestic use to screened or open-end wells. Recharge to these aquifers is mostly by leakage through overlying beds or by upward leakage from underlying beds where the piezometric surface of the Floridan Aquifer is above the piezometric surface in the shallow artesian aquifer. A small amount of water probably flows into the County from surrounding counties within the shallow artesian aquifers. Discharge from these aquifers is by downward leakage to the Floridan Aquifer, upward leakage to the non-artesian aquifer where the piezometric surface is above the water table, underground flow out of the County, and pumpage (Lichtler, et al., 1964).

The Floridan Aquifer, consisting of nearly 2000 feet of porous limestone and dolomite or dolomitic limestone covered
by sand and clayey sand ranging in thickness from a few feet to about 350 feet, is one of the most productive aquifers in the world. The total thickness of the Aquifer is not accurately known because the deepest water well in the County penetrates only the upper 1400 feet. The log of an oil test well drilled southeast of Orlando shows dense anhydrite at about 2000 feet, and this is assumed to be the base of the Aquifer.

The Floridan Aquifer in Orange County has two major producing zones that are separated by a relatively impermeable zone. The upper producing zone extends from about 150 feet below the land surface to about 600 feet. The lower producing zone extends from about 1100 feet to 1500 feet or more below the land surface. Both major producing zones are composed of hard brown dolomitic limestone or dolomite and relatively soft cream limestone; however, the top half of the upper zone is mostly soft limestone. Some of the dolomite in both major producing zones is very dense, but many interconnecting solution channels make the overall permeability of both zones very high (Lichtler, et al., 1968).

Solution channels, ranging in diameter from a fraction of an inch to many feet, probably occur throughout the Aquifer, but are most prevalent at depths between 200 and 600 feet and between 1100 and 1500 feet below the land surface. Cavities 15 feet or more in depth have been reported by drillers. Tests made by Unklesbay in 1943 show that wells with open holes between
depths of 60 and 450 feet and wells with open holes between 550 and 1000 feet below land surface have the same water level and fluctuate together, indicating that the solution channels are interconnected vertically as well as horizontally (Lichtler, et al., 1964).

The soft cream limestone in the top half of the upper zone contains solution channels, but they are usually neither as large nor as numerous as the channels in the dolomitic parts of either producing zone. At some locations, very large (4000 GPM or more) yields can be obtained from the soft limestone, but most high yield wells also penetrate the underlying dolomitic limestone. However, many domestic wells and small public supply wells draw their water from the soft limestone section of the upper zone. The municipal supplies for the cities of Orlando and Winter Park are developed in the lower producing zone of the Aquifer (1100-1500 feet). These wells generally yield 3-5,000 GPM with 10 to 25 feet drawdown (Lichtler, et al., 1968). Most other public supplies in Orange County are developed in the upper producing zone of the Floridan Aquifer.

The relatively impermeable zone (600-1100 feet) separating the two major producing zones is composed of relatively soft, mealy limestone and dolomitic limestone. It contains some water bearing layers, but generally this separating zone yields much less water than the zones above and below it. In many
parts of the County the separating zone would be considered a good aquifer, but because much larger supplies can be obtained above and below, very few wells are developed in it (Lichtler, et al., 1968).

The piezometric surface of the Floridan Aquifer in Orange County ranges from about 15 feet above to more than 60 feet below the land surface and slopes to the east and northeast from its highest point in the southwestern part of the County. The magnitude of fluctuations of the piezometric surface ranges from place to place in the County. The greatest fluctuations occur in Orlando, where more than 300 drainage wells in and around the City permit direct and immediate recharge to the Aquifer and where pumping is concentrated (Lichtler, et al., 1964).

The most effective recharge areas in the East Central Florida region are in Lake County and in the western part of Orange, Seminole and Volusia Counties. An isolated recharge area, which appears to be an extension of the Volusia County area, is in Eastern Seminole County (Lichtler, 1972). Most of the recharge to the Floridan Aquifer in Orange County is from infiltration of rain through the relatively thin semipermeable confining beds in the highlands section of the County and through drainage wells. A lesser quantity enters the County by underground flow from southern Lake County and from Osceola County (Lichtler, et al., 1964). The drainage wells have been installed
to convey surface water directly to the upper zone of the Aquifer. This is useful in providing recharge and maintaining ground water levels. However, there are very few controls on the quality of the water entering the Aquifer through these wells, and wide-spread pollution of the upper zone has resulted. Fortunately, the lower zone has not yet been polluted (Lichtler, 1972).

The quality of the water in the Floridan Aquifer ranges greatly throughout the County, but varies little at a particular location and depth. In the western part of the County, most of the water in the Aquifer is relatively low in mineral content, and the dissolved solids are less than 150 mg/l. The mineral content of the water increases toward the eastern part of the County, and the dissolved solids exceed 1000 mg/l in the flowing wells along the St. Johns River. The high mineral content of artesian water in the eastern part of the County is probably due to incomplete flushing of saline water that entered the Aquifer when the sea last covered Florida.

Lichtler states that except for high hardness, most water from the Floridan Aquifer in western and central Orange County is of good chemical quality. However, water from flowing wells to the east along the St. Johns River is very hard and contains large amounts of sodium, sulfate, and chloride (Lichtler, et al., 1964).

Hydrogen sulfide gas is generally present in water from flowing wells, and can be detected by the characteristic odor
and taste similar to rotten eggs. This gas has two possible sources in natural water. One is the reduction of sulfates by organic material under anaerobic conditions, resulting in the decomposition of metallic sulfide by free carbon dioxide. In some cases, hydrogen sulfide may be formed from the anaerobic reduction of organic matter with which the water comes in contact. The concentration of hydrogen sulfide in deep well water is highly variable, ranging from traces to over 4 mg/l. It may be eliminated by aeration (Lichtler, et al., 1968).

Succeeding chapters of this report show actual data from existing wells in Orange County. This data can be compared to the information from the literature that was researched to develop this chapter on hydrology.
CHAPTER III
ORANGE COUNTY POTABLE WATER SYSTEM

Development of the Water System

Orange County has been in the sewer business since 1958. It was not until 1972, however, that the County entered the water business. On February 8, 1972, the Orange County Commission created a Sewer and Water Advisory Commission, whose responsibility was the development, operation, and maintenance of adequate sewer and water systems within the unincorporated areas of the County.

On July 18, 1972, the Orange County Commission passed a Resolution requiring that all persons desiring to construct or expand a water or sewer system within the unincorporated areas of the County make application to the newly named Orange County Sewer and Water Department. This Ordinance was expanded on May 1, 1973, to require newly constructed water and/or sewer systems to be deeded to the County for ownership, operation and maintenance.

Then, based on Chapter 153 of the Florida Statutes, giving County governments the authority to purchase private or investor-owned water and/or sewer systems, the County set up an Acquisitions Commission for the purpose of acquiring private utilities serving the unincorporated areas of Orange County.
In July, 1973, a Water Treatment Superintendent was hired by the County to prepare for the acquisition of new water systems. The first system was obtained from Locke Well and Pump Company in January, 1974. This system was known as East Highlands and was located near East Colonial Drive and Chickasaw Trail. At that time, there were three employees in the Water Section.

It was not until late 1974 and early 1975 that the County acquired additional systems. At this time, they purchased the Vistana and Orangewood systems and increased the water section to five employees. Through the balance of 1975, the County's acquisitions flourished. Several individually owned water systems as well as the unincorporated Orange County properties of investor owned Southern Gulf Utilities and General Waterworks Corporation were acquired. By the end of 1975, the Water Section had twelve employees.

In 1976, another investor owned utility, Southern States Utilities, sold most all of their unincorporated Orange County properties to the County. In addition, two or three other small systems were acquired.

In 1977, the County bought the Orange County properties of First Florida Utilities and Central Florida Utilities, both of which owned numerous systems. By the close of 1977, there were twenty-nine employees in the Section.
At the present time, with the County owning fifty operational water plants, they are dormant in acquiring additional systems. There are some that are possible acquisitions in the future, but very few are probable. The operational structure is set up for thirty-five employees, although only thirty-two positions are actually filled. As the majority of the systems in unincorporated Orange County have been purchased, the present trend is to tie neighboring small systems together to form larger, more efficient systems.

Wells in the System

The Orange County water system is comprised of fifty active water treatment plants having sixty-four wells presently in service. In addition, there are another ten water treatment plants which have been phased out of service due to having their distribution systems interconnected with one or more other distribution systems which are serviced by active water treatment plants. The underlying reasons for interconnecting distribution systems and phasing out water plants are: less than acceptable water quality or unsatisfactory bacteriological samples from the wells; old, un-reliable equipment in service; and inadequate size or incompatibility with the pumping procedures used at a larger interconnected plant. There are at least thirty out-of-service wells located at the fifty active and ten inactive treatment plants.
Some references indicate other, older, wells existed at some of the plants, but no records of any data have been passed along to recent owners. Only the ninety-four wells having recorded data available are included in this report.

The water treatment plants are dispersed throughout unincorporated Orange County, generally encircling the urban area of the cities of Orlando, Winter Park and Maitland. The numbering system applied by the County to the various active plants is alphabetical in design. Both the active and inactive treatment plants are listed in Table III-1, and their locations are shown in Figure III-1. Also shown in Figure III-1 are present and former locations for official rainfall measuring points for the Orlando area. The former location, Herndon Airport, is labeled R1 and the present location, McCoy Jetport, is labeled R2.

The water plants have been geographically divided into five general areas for discussion and comparison in later sections of this report. These geographical areas are also shown in Figure III-1 and are labeled East, Southeast, West, Southwest and Far Northwest. A listing by geographical area is shown in Table III-2.

Data on each of the wells was compiled on a five-page form shown here as Table III-3. In very few cases was all desired data available for a given well. The form was designed, however, to log any information considered by the writer to be useful to Orange County or their consultants. Data was gathered on location;

original drilling of the well (date, driller, depth, casing, well screen, grouting, well log, etc.); static water level and pumping tests; chemical and bacteriological quality of the water; and most recent, if not present, pump, motor and auxiliary engine.

Some of the data collected, such as chemical analyses and well logs, was considered too voluminous to include in this report. If desired, however, it is available from the Orange County Sewer and Water Department or from the writer.

Data on static water level was compared to piezometric surface level maps obtained from the U.S. Geological Survey to check for accuracy and to Orlando rainfall records to ascertain if a correlation exists.

The next several chapters of this report discuss the data compiled and provide comparisons and similarities between wells in the various geographical areas.
CHAPTER IV
EAST AREA WELLS

Orange County owns, operates and maintains thirteen water treatment plants in the East Area, twelve of which are active. This area is bounded roughly on the north by University Boulevard, on the east by Percival Road, on the south by Lake Underhill Road, and on the west by Semoran Boulevard. At these thirteen plants, there are fifteen wells in service and five wells which are no longer in service. The treatment plants are listed in Table IV-1 and their locations are shown in Figure IV-1.

Table IV-2 gives elevation and depth data for the wells themselves, the casing pipe in each well and the static water level recorded in each well. Some data, as mentioned in Chapter I, was gathered from several references and is conflicting in nature. Some of the static water level data was recorded on more than one date for a given well. As is representative of all tables in this and succeeding chapters of this report, conflicting data or duplicated data is noted.

All of the well depths fall into the upper level of the Floridan Aquifer, with the deepest being 570 feet, the shallowest 180 feet, and the mean 373 feet from ground surface. Casing pipe depths, which represent the depth at which solid rock or an

* Readings taken on different dates

** Conflicting data from different references
aquiclude was reached casing out the ground water aquifer, range from 60 feet to 240 feet below ground surface, averaging 161 feet. Static water level depths range from 9 to 46 feet below ground surface, with the mean being 23 feet. These levels represent the artesian pressure of the water in the Floridan Aquifer at the particular well's location.

Comparing the static water level data collected to piezometric surface level maps from the U.S. Geological Survey (U.S.G.S.) indicated reasonable agreement for all but Well No. 2 at the inactive College Heights Water Plant. The recorded static water elevation of 46 feet MSL (measured September 23, 1975) appears to be approximately seven feet higher than that which would be predicted by the U.S.G.S. maps. It is noted that the U.S.G.S. maps showed variations of piezometric surface level elevations varying up to 25 feet over a seventeen year period for any particular well. As these elevations are so time dependent, very little significance can be given to the average static water level shown in Table IV-2.

Table IV-3 provides pumping data from the wells. The maximum known tested well flow is shown for each well, followed by its ratios to the well drawdown level (giving specific capacity), well circumference, and both drawdown and well circumference. Each of these ratios can be considered to represent the water bearing capacity of the aquifer at this location. A higher value of any of these ratios at one location over another could indicate more water may be obtained at that location than at the other one.

*Conflicting Data from different references*
Using the ratios having well circumference can be misleading, however. If two separate wells are both pumped to their limits, i.e., at volumetric rates approaching the maximum value for each well, the calculated ratios could be reasonably comparable. If, on the other hand, one of the wells is not pumped to its limit, a comparison to the other well would show a false relationship. For the data collected, there is no way to assure the volumetric flow rates tested were the maximum rates each well could produce. Therefore, the values shown for the two ratios reflecting the use of the circumference of each well cannot be used effectively. If new tests were run on these wells, allowing for maximum pumping rates to be determined, then the new ratios calculated could be useful in predicting the water bearing capacity of the formations.

Tested well flows in the east area ranged from a low of 35 gallons per minute to a high of 2500 GPM, with the mean being 768. For the wells with data available, specific capacity varied from 32.0 to 714.3 GPM per foot of drawdown, averaging 247.8. Flow per unit well circumference had a mean value of 22.55 GPM per inch, with a range of 1.86 to 53.04. Specific capacity per unit well circumference for the wells having data available ranged from 1.69 to 14.20 GPM per foot of drawdown per inch circumference, with a mean value of 5.92.

Table IV-4 compares concentrations of significant physical and chemical compounds recorded through chemical analysis of each

</table>
well. Although, in general, complete public water supply analyses, as required by the State of Florida Department of Environmental Regulation, were found for these wells, only those parameters which are most representative of potable water quality in the Central Florida area and that vary significantly from well to well are listed. Due to the voluminous nature of the complete chemical analysis, this data is not included with the individual data sheet shown for each well later in this chapter, and for other wells in succeeding chapters.

Florida potable water standards for the components shown in Table IV-4 are as follows (State of Florida Department of Environmental Regulation, 1981):

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Standard</th>
</tr>
</thead>
<tbody>
<tr>
<td>Total Dissolved Solids</td>
<td>500 mg/l maximum</td>
</tr>
<tr>
<td>Total Alkalinity</td>
<td>none established</td>
</tr>
<tr>
<td>Total Hardness</td>
<td>none established</td>
</tr>
<tr>
<td>Chloride</td>
<td>250 mg/l maximum</td>
</tr>
<tr>
<td>Sulfide</td>
<td>none established</td>
</tr>
<tr>
<td>Iron</td>
<td>0.3 mg/l maximum</td>
</tr>
</tbody>
</table>

In addition, the relative hardness of water, which is caused by the presence of alkaline earth metals such as calcium and magnesium (Lichtler, 1964) is generally defined as follows (Sawyer and McCarty, 1967):
Soft 0 - 75 mg/l as CaCO₃
Moderately Hard 75 - 150 mg/l as CaCO₃
Hard 150 - 300 mg/l as CaCO₃
Very Hard more than 300 mg/l as CaCO₃

As can be seen from the table, all wells are within the established limits for total dissolved solids and chloride. All are within the hardness classifications of either moderately hard or hard. In general, hardness levels in the range found are not treated to reduce their values in the Orange County area. Iron levels are at or above the established limits for Plant No. 2 (Arcadia Acres), Well No. 1 at Plant No. 18 (Hilltop Manor), and Plant No. 23 (Lee Estates). These levels of iron can be easily reduced by treatment in order to be within the established standard.

Available records of bacteriological tests run in accordance with state requirements, which indicate the level of coliform bacteria in potable water sources, show that Well No. 1 at Plant No. 42 (Tiffany Terrace) has had a history of tests with unsatisfactory results. The records available indicated eight unsatisfactory samples spread out over an eight month period. The Orange County Sewer and Water Department was unable to provide a reason for these unsatisfactory samples, but also did not feel overly concerned that a problem existed at this well (Stewart, 1981). All other wells in the east area have a history of satisfactory results.
Individual data sheets for each of the wells in the east area are shown in the following pages.

CHAPTER V
SOUTHEAST AREA WELLS

There are twelve water treatment plants in the southeast area, eight of which are active. At these plants there are eleven wells presently in service and twelve which are not in service. The area is bounded by Lake Underhill Road on the north, Econlochatchee Trail on the east, McCoy Road on the south, and Orange Avenue on the west. These treatment plants are listed in Table V-1 and their locations are shown in Figure V-1.

Table V-2 shows elevation and depth data for each well, the well's casing pipe, and its static water level. All but two of the wells penetrate only the upper level of the Floridan Aquifer. The wells from Plant No. 3 (Azalea Park) and Plant No. 36 (Rio Pinar) penetrate the lower level of the aquifer. The deepest of the wells in the upper level of the Aquifer is 685 feet. The shallowest well is 210 feet deep and the mean is 342 feet below the surface when not including the lower level of the Aquifer. Casing pipe depths average 160 feet when not including the lower level, with the deepest being 305 feet and the shallowest 70 feet. Static water level depths ranged from 27 to 66 feet below ground service, with the mean being 42 feet. A comparison to U.S.G.S. piezometric surface level maps indicated reasonable

* Readings taken on different dates
** Conflicting data from different references
***Not including lower Floridan Aquifer values
agreement in all cases except Well No. 1 at the inactive Conway Hills Plant. The reading of 76 feet MSL recorded in 1962 exceeds the highest value of surface water level shown for this location on the available U.S.G.S. maps (September, 1960 - 67 feet MSL). It is the writer's opinion that the value recorded for this well and shown on the data sheet is an erroneous number.

Table V-3 indicates pumping data from each well. Tested pumping rates in this area ranged from a low of 60 GPM to a high of 3,000 GPM, with the mean being 637. Available data from the wells indicate specific capacity varies from 53.9 to 103.4 GPM per foot drawdown, averaging 82.4. Flow per unit well circumference has a mean value of 21.31 GPM per inch, with a range of 3.18 to 83.56. Specific capacity per unit well circumference ranges from 0.85 to 3.58 GPM per foot of drawdown per inch circumference, with an average value of 1.57.

Table V-4 gives chemical data for the wells in the southwest area. All wells are within the established limits for total dissolved solids and chloride. All are within the hardness classifications of either moderately hard or hard, with the hardest being 207 mg/l. Iron levels are at or above the limits for Well No. 1 at Plant No. 15 (Graham Gardens) and Well No. 1 at the out-of-service Robinsdale Plant.

Bacteriological test results indicate there has been a history of unsatisfactory levels of coliform bacteria in Well No. 1 at
Plant No. 15 (Graham Gardens) and in Well No. 1 at Plant No. 40 (Shady Acres). Several drainage wells are located near the Graham Gardens Water Plant, including one within 500 feet. It is the opinion of the Orange County Sewer and Water Department that pollutants deposited into these wells over the years have caused the unsatisfactory samples. No explanation could be offered for the Shady Acres Water Plant, but the Department is not overly concerned that a problem exists at this plant (Stewart, 1981).

Individual data sheets for each of the southeast area wells are included in the following pages.

CHAPTER VI
SOUTHWEST AREA WELLS

The southwest area has nine active and one inactive water treatment plants. At these plants, there are nine wells presently in service and two which are no longer in service. The area is bounded by Roberts Road on the north, Kirkman Road and Shingle Creek on the east, Vistana Boulevard on the south, and Lake Butler on the west. These plants are listed in Table VI-1 and their locations are shown in Figure VI-1.

Table VI-2 provides elevation and depth data for these wells. All of them penetrate the upper level of the Floridan Aquifer, with the deepest being 580 feet, the shallowest 150 feet, and the mean 368 feet below ground surface. Casing pipe depths range from 119 feet to 219 feet below the ground surface, averaging 166 feet. At the time static water table depths were measured, they ranged from 24 to 88 feet below ground surface, with the mean being 38 feet. All static water level values are in reasonable agreement with levels shown on U.S.G.S. piezometric surface level maps.

Table VI-3 gives pumping data for the wells. The mean flow rate was computed to be 725 GPM, with the range being from 40 to 2500 GPM. For the wells from which data was available, the specific capacity varied from 71.4 to 500.0 GPM per foot of drawdown,

* Conflicting data from different references. **Readings taken on different dates.
with the average being 256.4. Flow rate per unit well circumference ranged from 3.98 to 49.74 GPM per inch, with the mean being 19.99. Specific capacity per unit well circumference for the wells with data available varied from 1.89 to 9.96 GPM per foot of drawdown per inch circumference, averaging 5.89.

Table VI-4 provides chemical data for these wells. All are within the established limits for total dissolved solids and chloride. They all have hardness levels within the classifications of moderately hard or hard, with the softest being 102 mg/l and the hardest being 234 mg/l. Iron levels are generally within the established limits, with Plant No. 12 (Down Point) being at the limit and Plant 49 (Windermere Downs) being slightly over the limit at 0.4 mg/l.

Available records of bacteriological tests do not indicate histories of unsatisfactory levels of coliform bacteria in this area.

Individual data sheets for each well in the southwest area are shown on the following pages.

CHAPTER VII
WEST AREA WELLS

There are nineteen water treatment plants in the west area, fifteen of which are active. At these plants, there are twenty-two wells presently in service and ten wells which are not. The area is bounded by Oranole Road (the Orange-Seminole County line) and Keene Road on the north, Forest City Road and John Young Parkway on the east, Old Winter Garden Road and Sunshine State Parkway on the south, and Lake Apopka on the west. These treatment plants are listed in Table VII-1 and their locations are shown in Figure VII-1.

Table VII-2 shows elevation and depth data for each well, the well's casing pipe, and its static water level. Most of these wells appear to penetrate the upper level of the Floridan Aquifer. Four of these, two at Plant 50 (Woodsmere Manor) and two at inactive Ridge Manor have depths generally considered less than the depth to the beginning of the Floridan Aquifer (150 feet below ground surface). The shallowest of these is 100 feet deep. Each of these wells has casing pipe installed to depths of approximately 75 to 80 feet, which would indicate the groundwater aquifer has been cased out to avoid any pollutant from this level reaching

** Readings taken on different dates
the potable water source. It would appear that these four wells penetrate a shallow artesian aquifer located between the non-artesian aquifer and the Floridan Aquifer.

The deepest well in this area is 609 feet below the ground surface. The mean depth is 316 feet. Casing pipe depths average 138 feet, with the deepest being 447 feet and the shallowest 63 feet. Static water level depths at the time of measurement ranged from 15 to 75 feet below ground surface, with the mean being 42 feet. Comparing these static water levels to contours shown on U.S.G.S. piezometric surface level maps show reasonable agreement in all cases except Plant No. 24 (Magnolia Woods). The values recorded of 43 and 25 feet MSL (52 and 70 feet below ground surface, respectively) on unknown dates are far below the lowest elevation shown on a U.S.G.S. map of 63 feet in May, 1974. The values shown with the data sheets appear to be erroneous.

Table VII-3 indicates pumping data from each well. Tested pumping rates in this area ranged from a low of 20 GPM to a high of 3100 GPM, with the mean being 431. Available data from the wells indicate specific capacity varies from 40.0 to 6200.0 GPM per foot of drawdown, averaging 1096.7. Flow per unit well circumference has a mean value of 14.93 GPM per inch, with a range of 1.06 to 63.66. Specific capacity per unit well circumference ranges from 1.66 to 123.36 GPM per foot of drawdown per inch circumference, with an average value of 22.87.

* Conflicting data from different references.
Table VII-4 gives chemical data for the wells in the west area. All wells are within the established limits for total dissolved solids and chloride. All are within the hardness classifications of either moderately hard or hard, with two of the wells having values less than 100 mg/l. Iron levels are well above the limits for both wells at Plant No. 30 (Partlow Acres) and for Well No. 1 at Plant No. 50 (Woodsmere Manor). Well No. 2 at Plant No. 50 did not have chemical data available.

Bacteriological test results indicate past unsatisfactory levels of coliform bacteria in Well No. 1 at Plant No. 6 (Clearview Heights) and in Well No. 1 at Plant No. 25 (Meadowbrook Annex). The unsatisfactory results at Clearview Heights occurred during the period immediately after replacing the well pump. According to the Orange County Sewer and Water Department, the well was not disinfected properly during the replacement process. After many unsatisfactory results, the pump was removed, the well re-disinfected, the pump reinstalled, and the well cleared. Well No. 1 at Meadowbrook Annex has a continuous bacteriological problem. There are ten drainage wells of approximately 150 feet depth within a 1½ mile radius. The Meadowbrook Annex well is cased to 65 feet and has a total depth of 225 feet. When it was drilled, a water bearing cavity was penetrated at the 120 feet level. Each year after commencement of the wet season, the unsatisfactory bacteriological samples begin to occur. It is the feeling of the

CHAPTER VIII
FAR NORTHWEST AREA WELLS

Orange County owns, operates, and maintains six water treatment plants in the far northwest area, all of which are active. This area is bounded roughly by Ondich Road on the north, Wekiwa Springs Road on the east, Semoran Boulevard on the south, and Hermit Smith Road on the west. At these six plants, there are seven wells in service and one well out-of-service. The treatment plants are listed in Table VIII-1 and their locations are shown in Figure VIII-1.

Table VIII-2 gives elevation and depth data for the wells themselves, the casing pipe in each well, and the static water level recorded in each well. Most of the wells fall into the upper level of the Floridan Aquifer. The deepest is 460 feet below the ground surface. The shallowest, Plant 26 (Mount Plymouth Lakes) at 127 feet below ground surface, is similar to the wells at Plant 50 and inactive Ridge Manor in the west area in that it is more shallow than generally considered necessary to penetrate the Floridan Aquifer. This well is probably also penetrating a shallow artesian aquifer. The mean value of well depth is 279 feet below ground surface.

* Readings taken on different dates
** Conflicting data from different references
Casing pipe depths vary from 50 to 127 feet below ground with the average being 94 feet. Static water level depths range from 40 to 90 feet below ground surface, with the mean being 57 feet. All static water level values shown are in reasonable agreement with levels recorded on U.S.G.S. piezometric surface level maps.

Table VIII-3 provides pumping data from the wells. Tested flows in the far northwest area ranged from a low of 75 gallons per minute to a high of 500 GPM, with the mean being 282. For the wells with data available, specific capacity varied from 50.0 to 83.3 GPM per foot of drawdown, averaging 69.1. Flow per unit well circumference had a mean value of 13.06 GPM per inch, with a range of 5.97 to 19.89. Specific capacity per unit well circumference for the wells having data available ranged from 1.98 to 3.32 GPM per foot of drawdown per inch circumference, with a mean value of 2.75.

Interestingly, the high values for each of the well flow categories are from Plant No. 26, the well with depth of 127 feet. This would show that the shallow artesian aquifer has the potential in certain locations to be very productive.

Table VIII-4 compares concentrations of physical and chemical compounds recorded through chemical analysis of each well. All wells are within the established limits for total dissolved solids and chloride. As with all other areas, all wells are within the hardness classifications of either moderately hard or hard.

The iron level is slightly above the established limit at Plant No. 32 (Plymouth Heights).

Available records of bacteriological tests indicate there has been a history of unsatisfactory results at Plant No. 26 (Mount Plymouth Lakes), Plant No. 33 (Plymouth Hills), and Well No. 2 at Plant No. 39 (Rock Springs). The unsatisfactory test results occur each year during the dry season only at Mount Plymouth Lakes. The only explanation offered by the Orange County Sewer and Water Department is that a nearby lake tends to recharge the aquifer at the well's location when the piezometric surface elevation recedes during the dry season. Well No. 2 at Rock Springs incurred unsatisfactory results from stagnated water caused by only occasional use and due to a partial casing collapse. The well has since been taken out of service. No explanation could be offered for the unsatisfactory results at Plymouth Hills (Stewart, 1981).

Individual data sheets for each of the wells in the far northwest area are shown in the following pages.
Plant Name: No. 26 - Mount Plymouth Lakes

CHAPTER IX
SUMMARY AND CONCLUSIONS

Data Comparison by Geographical Area

Data compiled and shown in previous chapters by geographical area has been used to prepare a series of graphs comparing mean, high and low values of the various parameters according to their geographical area. These graphs indicate any significant variation that may exist in the public water supply throughout the different areas in Orange County.

Figure IX-1 compares mean, deepest, and shallowest values of total well depth, both by depth from surface and by mean sea level elevation. The graphs are constructed eliminating the wells penetrating the lower level of the Floridan Aquifer in the southeast area of the County for comparison of the upper levels of the Floridan Aquifer and any shallow artesian aquifers only. The graph shows that, in general, the wells become slightly shallower as you progress from east to west across the County, both from surface level and by actual elevation. This would indicate that water is available closer to the surface and at an elevation closer to sea level in the western part of the County than in the eastern part, but not necessarily in larger volumes.
Fig. IX-1. Comparison of Orange County well depths by geographical area.

--- Depth from surface ---- Elevation MSL
Figure IX-2 gives similar information for well casing depths. Correlation is not as well defined here. Although the mean values of both depth from surface and mean sea level elevation are slightly shallower as you progress from east to west, the deepest and shallowest values fluctuate in no apparent pattern. The deepest casing pipe is found in the westerly area. This might indicate that the non-artesian shallow ground water aquifer, in general, has a bottom slightly closer to the surface and at a higher elevation in the west than in the east, but that the formation is somewhat fractured allowing this aquifer to extend much deeper in particular locations.

Figure IX-3 compares static water level, representing the piezometric surface of the Aquifer at a particular location, for the various areas of the County. Only deepest and shallowest values are plotted, as mean values have little significance due to the dependence on time of measurement for specific locations. Fluctuations of up to 25 feet at a particular well were noted over a period of time as shown on U.S.G.S. piezometric surface level maps. This is an important point to keep in mind when selecting the length of column pipe while designing a well. In general, the graph shows an increasing depth from surface to the static water level as you progress from east to west. As measured from sea level, the highest elevations occur in the southwest area which is in agreement with the literature. The
Fig. IX-2. Comparison of Orange County well casing depth by geographical area.

--- Depth from surface  ---- Elevation MSL
Fig. IX-3. Comparison of Orange County well static water levels by geographical area.
lowest elevations appear to occur in the east, west and far northwest areas with no real differentiation. This differs somewhat from the literature which states that the piezometric surface slopes down to the east and northeast. It is probable that the random values available for the graph shown are not completely representative of the actual condition of the Floridan Aquifer.

Table IX-1 provides official rainfall data between the years 1945 and 1980 for the Orlando area (U.S. Department of Commerce, 1978, 1979 and 1980). Correlations between static water levels and rainfall were attempted without much success. One reason for this is that the recorded rainfall may or may not be representative of the rainfall actually occurring near a particular well site. The locations for official rainfall sampling are listed in Table IX-1 and are shown in Figure III-1. These locations are a significant distance from many of the wells and the corresponding rainfall may also be significantly different.

Figure IX-4 compares specific capacity for the five areas. Comparison of the values for specific capacity, as discussed in Chapter IV, is the only significant comparison for the data collected and is, therefore, the only one plotted. The other relationships involving well circumference can be misleading as it is unknown if each well has been pumped to its limit. Even the comparison for specific capacity does not present a realistic situation due to the limited data which was available. The data

Fig. IX-4. Comparison of Orange County well pumping specific capacities by geographical area.
available indicates by far the highest values for specific capacity are in the westerly area, with the lowest and most consistent levels being in the southeast and far northwest areas.

Figures IX-5 through IX-7 compare water quality parameters for the areas. Figure IX-5 shows total dissolved solids and chloride concentrations. There is not much variation noted through the five areas of the County system. There is, however, some variance with values shown in the literature and discussed in Chapter II. None of the wells owned by Orange County are in the far easterly area near the St. Johns River where high mineral contents of wells have been noted in the literature. The wells in Orange County's system extend from approximately the middle of eastern Orange County to the far western border. The literature indicates the level of mineral content, particularly in the western part of the County, is low; with values of total dissolved solids below 150 mg/l (Lichtler, et al., 1964). Data obtained from this study showed only one well in the entire system with a concentration as low as 150 mg/l. The mean value was lowest in the west, with a value of 198 mg/l. All areas, including the west, had levels in some wells exceeding 300 mg/l.

Figure IX-6 shows comparisons for total alkalinity and total hardness. The highest values appear to be in the east area, with not a great deal of fluctuation throughout the County.

Iron            ------- Sulfide
Figure IX-7 compares concentrations of iron and sulfide. This graph shows both substances are highest in the east and reduce as you progress to the west.

**Recommendations for Additional Studies**

This report has been a research study to collect and compare data on public water supply wells owned by the Orange County government. No attempt has been made to run tests or obtain original data from field observation of the Orange County system or to obtain information on nearby wells owned by entities other than Orange County.

Further studies are recommended which would add to and clarify the data already accumulated, thereby giving more significance to the comparisons attempted in this chapter.

The studies recommended are two-fold. The first would best be undertaken by Orange County, or a consultant obtained by them. This would involve field verification of data previously accumulated and the addition of data not available in existing files or literature on the Orange County system. Recommended testing would include the chemical analyses of water samples, electronic well logs, and pump and well flow tests, including static water level and drawdown determination over a short period of time for significant comparison. The second recommended study is a similar research report to this one for other wells in the Orange County region, such as those owned by adjacent cities and private
or investor owned utility companies. This second study could be expanded to include the same field determination and testing as that recommended for the Orange County system.
